For bone tumours, plain film x-rays are the most informative, but appropriate scans are required for further confirmation and staging.

Imaging should always include the whole of the affected bone to look for satellite lesions and skip metastases. Satellite lesions occur within, while skip lesions occur beyond the reactive zone of the tumour.

Both primary bone sarcomas and soft tissue sarcomas commonly metastasise to the lungs and a CT scan is an essential part of the staging.

Patients who present with a lytic bone lesion could have a renal primary and an ultrasound scan of the kidneys is advised. Biopsy without this could result in unexpected massive blood loss (Summary box 39.9).

Summary box 39.9

Staging

- Plain x-ray is most informative for bone tumours
- Always image the whole bone in case of skip lesions
- CT of the lung detects lung metastases
- Lytic lesions require ultrasound abdomen to check for a renal primary

Biopsy

A biopsy is performed only when the staging process is completed. This should be carried out in the centre performing the definitive surgical procedure.

Image-guided biopsies have a higher diagnostic accuracy as areas of radiological concern can be targeted. If image-guided biopsy is performed, close discussion between radiologist and surgeon is required to ascertain that the correct biopsy route is used. It is essential that the biopsy track is excised at the time of definitive surgery (Figures 39.26 and 39.27).

Biopsies for bone tumours are usually taken using a Jamshidi needle (Figure 39.28), while Trucut needles are preferred for soft tissue tumours.

Principles of biopsy

- A tourniquet can be used; but exsanguination should be avoided as this can release tumour cells in the circulation.
- Use longitudinal incisions that are part of an extensile approach.
- Do not cross compartments.

- Biopsy track will have to be excised at the time of definitive surgery (Summary box 39.10).

Summary box 39.10

Biopsy

- Only biopsy once staging is completed
- Biopsy should be performed at the centre undertaking the main surgery
- Image-guided biopsy is more reliable
- The biopsy track must be excised at definitive surgery
- Jamshidi needles for bone, Trucut needles for soft tissues

Figure 39.26 Poorly placed biopsies, making subsequent surgical excision of the track impossible.

Figure 39.27 En bloc excised tumour and biopsy track.

Figure 39.28 Bone biopsy instruments.

Assessment

The assessment of any bone or soft tissue lesion can be divided into three phases. The first two phases can be performed in a district general hospital, but the third phase is best carried out in a tumour treatment centre (Table 39.5).

Table 39.5 The three phases of assessment of lesions.

Phase 1 (within 24 hours)	Phase 2 (within first week)	Phase 3 (at tumour centre)
History and examination	Bone scan	CT-scan lesion
Bloods	Ultrasound scan abdomen	MRI-scan lesion
X-ray whole bone Chest x-ray	CT-scan chest	Biopsy

CT, computed tomography; MRI, magnetic resonance imaging.

Patients with metastatic disease often require resuscitation for electrolyte imbalance, anaemia, cardiorespiratory problems or hypercalcaemia before surgical treatment can be considered. Hypercalcaemia can be treated effectively with fluid resuscitation and pamidronates.

The risk of pathological fracture needs to be assessed. This is best assessed using the Mirel score (Table 39.6).

Table 39.6 The Mirel's scoring system for risk of pathological fracture.

	Score		
	1	2	3
Site	Upper limb	Lower limb	Peritrochanter
Pain	Mild	Moderate	Functional
Size	<1/3	1/3–2/3	>2/3
Lesion	Blastic	Mixed	Lytic

Score >8, high risk of fracture – urgent prophylactic treatment needed; score <7, low risk of fracture – stabilization of the bone not immediately needed.

TREATMENT/PROGNOSIS/COMPLICATIONS

Primary bone tumours

Most latent and active benign bone tumours are treated by intralesional curettage. Packing of the cavity with graft of bone substitutes is usually not required.

Simple bone cysts can heal following pathological fracture and an initial observant approach following fracture is best. If the cyst persists following union of the fracture, a variety of treatments including injection with steroid or bone marrow and surgical curettage have been described.

Osteoid osteomas can resolve spontaneously. However, symptoms are often pronounced and most patients are treated by CT-guided thermocoagulation.

Large or more rapidly growing benign bone tumours might require more extensive surgical excision and reconstruction.

Malignant primary bone tumours require a more aggressive approach. Osteosarcoma and Ewing's sarcoma are treated with neoadjuvant chemotherapy and surgery. Chondrosarcomas are not sensitive to chemotherapy or radiotherapy and treatment is surgical.

The surgical options for malignant primary bone tumours are:

- amputation or van Ness rotationplasty;
- excision alone (for dispensable bones);
- excision and replacement with graft or prosthesis.

If surgery excision is undertaken it is important for the biopsy track to be excised 'en bloc' with the surgical specimen to avoid local recurrence through the biopsy track.

Following excision the resection margins can be classed as in Table 39.7.

In most cases, limb salvage with excision and reconstruction is possible (Figure 39.29). Only a minority of cases have neurovascular invasion and require amputation. Limb salvage, as compared to amputation, has a slightly higher rate of local recurrence. However, no difference in overall survival has been demonstrated (Summary boxes 39.11 and 39.12).

Table 39.7 Classification of surgical resection margins.

Surgical margins	
Intralesional	Resection through the lesion
Marginal	Resection through the reactive zone of the tumour
Wide	Resection outside the reactive zone of the tumour
Radical	Excising the whole affected compartment

Figure 39.29 Endoprosthetic replacement of the distal femur.

Summary box 39.11**Treatment – benign bone tumours**

- Benign lesions can be simply curetted
- CT-guided thermocoagulation is used for osteoid osteoma
- Large benign tumours may require reconstruction

Summary box 39.12**Treatment – malignant bone tumours**

- Osteosarcomas and Ewing's sarcoma require neoadjuvant chemotherapy
- Chondrosarcomas are insensitive to radiotherapy or chemotherapy
- Most malignant tumours can be treated with limb salvage
- There is no difference in survival between amputation and limb salvage

Metastatic bone tumours

Surgical treatment in patients with metastatic bone disease is palliative. This should be kept in mind when planning treatment. Surgery is unable to lengthen life in patients with metastatic bone disease, but can shorten it.

Spinal surgery may be required for stabilisation of the spine and/or decompression of patients with (impending) cord compression.

Surgery in the peripheral skeleton is mainly for treatment of (impending) pathological fracture.

Renal metastases tend to be very vascular and massive blood loss can be encountered during surgery. Therefore, preoperative embolisation should be considered just before surgery to prevent blood loss (Figure 39.30).

Treatment of myeloma is mainly haematological. Surgical

treatment is only required for complications such as fracture and spinal cord compression. Solitary plasmacytoma is an exception and surgical excision is usually advised.

Patients with a previous history of malignancy may present with a (solitary) bony lesion or pathological fracture. It should not be assumed that this is a metastatic lesion. Prior to planning surgical treatment it is important to ascertain the diagnosis is correct. Staging including biopsy will be required to exclude a malignant primary bone tumour.

Prior to planning surgical treatment for patients with metastatic bone disease it is important to have an assessment of:

- survival
 - prognosis of the primary tumour (Figure 39.31)
- quality of life
- medical fitness
- biomechanical/risk of fracture
- single or multiple bone lesions
- response to adjuvant treatment such as radiotherapy and hormonal treatment
- radiotherapy can be administered pre- or postoperatively.

Figure 39.31 Survival curves of patients who present with bony metastasis.

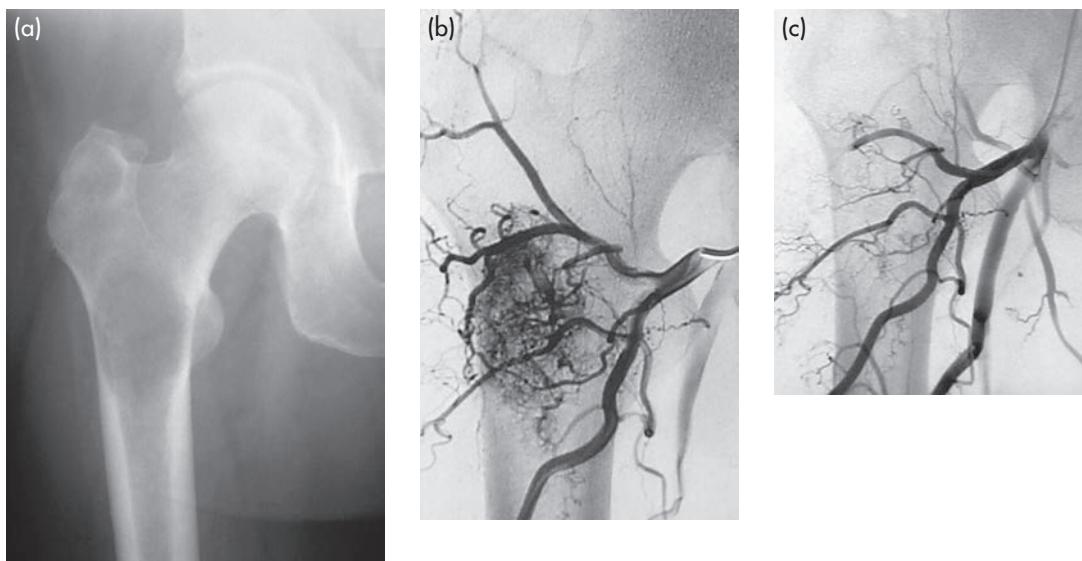

Figure 39.30 (a) Lytic metastasis of renal cell carcinoma. (b) Angiogram shows increased vascularity. (c) Following embolisation.

It is difficult to give strict guidelines for the surgical management of patients with metastatic bone disease. However, when a prolonged disease-free interval is expected, prosthetic replacement is usually preferred to intramedullary nailing. Particularly in patients with a longer life expectancy, a high failure rate is associated with internal fixation of pathological fractures.

Prior to surgical treatment it is essential to stabilise the patient's medical condition. Pamidronates can have a dramatic effect and might make surgery unnecessary.

Epiphyseal and metaphyseal lesions are best treated with prosthetic replacement; while diaphyseal lesions are usually best treated with an intramedullary nail. In the shoulder, prosthetic replacements have a poor function and internal fixation usually gives the best results. However, in hip lesions the best treatment usually is joint replacement.

Solitary breast and renal metastases can have a prolonged disease-free survival so excision and replacement rather than fixation should be the treatment of choice (Summary box 39.13).

Summary box 39.13

Treatment of bone metastases

- Surgery cannot lengthen life but may shorten it
- Spines may need stabilising and nerves or the cord decompressing
- Long bones will need stabilising if a pathological fracture is imminent
- Patients who have a possibility of long survival may need a prosthesis
- Radiotherapy relieves pain

Soft tissue tumours

Malignant soft tissue tumours are preferably excised with as wide a margin as possible. As in bone tumours, it is important for the

biopsy track to be excised *en bloc* with the surgical specimen (Figure 39.27). The skin might require reconstruction with a split skin graft or skin flap. In general, skin flaps are preferred as they allow for early administration of radiotherapy. Following surgical excision of high grade soft tissue sarcomas, adjuvant radiotherapy should be considered. Preoperative radiotherapy can also have good results, but there is a risk of wound healing problems following surgery. Chemotherapy has a limited role in the treatment of soft tissue sarcomas.

ACKNOWLEDGEMENTS

Parts of this chapter were previously published in the 24th edition of this book under the title Diseases of Bones and Joints, written by Tony Berendt and Martin McNally. Their material has been added to and updated by the new authors. Diagrams have been drawn from sketches by Mr Andy Biggs, RJA Orthopaedic Hospital, Oswestry.

LEARNING OBJECTIVES

To understand:

- Characteristic features in the history and examination of infection of bone and joint

- Treatment of infection of bone and joint

INTRODUCTION

Osteomyelitis is an old disease, identified in dinosaur bones, early hominids and skeletons from ancient civilisations. It can present acutely with major systemic upset, local inflammation and purulence, or insidiously, with gradual bone destruction, variable symptoms and prolonged chronicity.

The pattern of bone infection is changing. Worldwide, childhood acute haematogenous osteomyelitis and septic arthritis are common, with chronic disease following inadequate initial management. In the developed world, bone infection is now mostly seen after injury or surgery (contiguous focus osteomyelitis) and is often implant-related (Figure 40.1). The high number of patients with comorbidities (diabetes, peripheral vascular disease, immunocompromise), more frequent bone and joint surgery and longer population survival have produced a group of patients with increased susceptibility to infection. The incidence of bone and joint infection is likely to increase in the future.

Figure 40.1 Osteomyelitis of the distal tibia after a fracture with sinus formation and surrounding skin infection.

General principles: pathology

Acute osteomyelitis occurs when pathogenic bacteria cause inflammation in the bone and surrounding tissues. The medullary bone may form abscesses and the infection may track through the cortex to form periosteal elevation and soft-tissue extension. This process will devascularise the bone causing bone death which is the characteristic feature of chronic osteomyelitis (Summary box 40.1).

Summary box 40.1

Epidemiology of bone infection

- Bone and joint infections from haematogenous spread are now less common
- The increased use of implants for joint replacement and fracture fixation are a new source
- Immunocompromised patients, e.g. diabetes are another increasing source

Many bacteria can adhere to dead bone or implant surfaces, forming a complex community enveloped in a polysaccharide matrix, known as a biofilm. These bacteria alter their metabolic state, becoming resistant to the host immune system and to antibiotics.

The infected bone reacts to the infection by separating off dead fragments of bone (sequestration) and forming sinuses to drain pus and discharge small bone fragments. New bone is laid down around the infection from the periosteum (involucrum) (Figure 40.2).

In septic arthritis, infection may follow direct ingress of bacteria after injury or surgery, or may result from discharge of an adjacent acute osteomyelitis into the joint. In neonates or the elderly, bacteraemia may infect a previously normal joint. Toxins and lytic enzymes from bacteria cause early damage to articular cartilage (Summary box 40.2).

Figure 40.2 X-ray of chronic infection of the femur with a large central sequestrum and well-developed involucrum.

Summary box 40.2

Pathology of bone infection

- Bacteria infecting bone form a protective bio-film
- Infected bone dies and forms a sequestrum
- The periosteum around lays down new bone – an involucrum

General principles: microbiology

Virulent Gram-positive organisms, particularly *Staphylococcus aureus*, are the most common cause of bone or joint infection in native tissue. However, once prosthetic material is implanted, a wide range of organisms can be involved. This includes organisms with low virulence that are usually considered skin commensals, such as coagulase-negative staphylococci and propionibacteria (Table 40.1).

General principles: diagnosis

Clinical

Diagnosis is predominantly clinical with confirmation using other diagnostic tests.

Table 40.1 Organisms most commonly involved in bone and joint infection.

Gram-positive	<i>Staphylococcus aureus</i> (most common across all settings)	
	Coagulase-negative staphylococci (in implant-associated infections)	
	Streptococci	<i>Strep. pneumoniae</i> Beta-haemolytic streptococci <i>Strep. viridans</i> (in implant-associated infection)
Gram-negative	Enterobacteriaceae	<i>Escherichia coli</i> (especially at extremes of age) <i>Klebsiella</i> species <i>Salmonella</i> species (associated with sickle cell disease)
	<i>Pseudomonas</i> species	
	<i>Haemophilus</i> species	<i>H. influenzae</i> (consider in non-immunised children)
	<i>Neisseria</i> species	<i>N. meningitidis</i>
		<i>N. gonorrhoeae</i> (consider risk factors for sexually transmitted infection)
Others	Anaerobes	
	Fungi	(cause infection in immunocompromised hosts)
	Mycobacteria	<i>Mycobacterium tuberculosis</i> Atypical mycobacteria
Mixed	Any combination of the above	
'Culture negative'	No growth from cultures, but diagnosis of infection made on clinical/radiological/histopathological grounds	

Biomarkers

Raised inflammatory markers (erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and white cell count (WCC)) are characteristic of acute infection, but they are neither sensitive nor specific. These tests cannot rule in or rule out infection.

Imaging

Plain x-rays can only detect extensive bone loss, and cannot be relied on, especially in early disease. Plain x-rays are useful in evaluating implant loosening and progression of chronic disease.

Ultrasonography is ideal for identifying soft-tissue collections and can be used to guide bone biopsy and aspiration.

Computed tomography (CT) scans are helpful in assessing bone union of infected fractures. Small sequestra and cortical erosions are best seen with CT (Figure 40.3a).

Isotope bone scans are of very limited value as they are non-specific.

Magnetic resonance imaging (MRI) is the investigation of choice. It is highly sensitive and specific, showing all components of the disease (Figure 40.3b) (Summary box 40.3).

Figure 40.3 (a) Transverse computed tomography (CT) scan of femur with central sequestrum, sinus and cortical bone erosion. (b) Magnetic resonance imaging (MRI) scan of the same femur with better resolution of medullary infection and soft-tissue involvement.

Summary box 40.3

Investigations in bone infection

- ESR and CRP are neither sensitive nor specific in making a diagnosis of bone infection
- X-ray can only identify major bone loss
- Ultrasound is valuable for identifying collections of pus
- MRI is the investigation of choice in bone infection

Tissue sampling

Superficial samples and swabs from wounds or spontaneously draining pus are unreliable, since the organisms colonising the surface may bear no relation to those causing the invasive infection in the deeper tissues and bone. Microbiological samples may be falsely negative if antibiotics are given first. The histological diagnosis of infection (rather than other sources of inflammation) depends on identifying a neutrophilic infiltrate. However, such an infiltrate may be patchy and so histological studies are incompletely sensitive. Synovial tissue samples are particularly important in producing a higher diagnostic yield for infection with mycobacteria or fungi.

In complex infections, particularly those involving prosthetic material, multiple biopsy samples are needed to help determine whether organisms such as coagulase-negative staphylococci are likely to be the causative pathogens, or whether they are simply contaminants from the skin. This distinction cannot be made on a single sample, but the growth of an indistinguishable organism from three or more culture samples is 94 per cent specific for infection (Summary box 40.4).

Summary box 40.4

Identifying the organism in osteomyelitis

- Superficial swabs are of no value in identifying the organism involved
- If the patient is on antibiotics specimens may give a false negative
- A neutrophil infiltrate on histology is diagnostic of infection
- Multiple biopsy specimens are needed for reliable diagnosis

General principles: surgical management

Successful surgical treatment relies on the delivery of a few basic principles. These are:

- Preoperative
 - Patient assessment and clinical staging of disease
 - Full discussion of all treatment options with potential complications
 - Diagnostic tests for general health
 - Optimisation of patients and treatment of comorbidities
- Operative
 - Exposure for multiple, deep bone sampling
 - Excision of all affected tissue
 - Intravenous antibiotics after sampling
 - Bone stabilisation, if necessary
 - Dead space management
 - Soft-tissue cover which may include plastic surgery

- Postoperative
 - Functional rehabilitation
 - Continued antimicrobial therapy guided by culture results

General principles: antibiotic choice

If possible, patients should stop antibiotics 2 weeks before biopsy or surgery.

It is essential that patients with septic shock receive prompt empiric antibiotic therapy. However, whenever possible antibiotics should be delayed until microbiological samples have been taken (especially when prosthetic material is involved). When delay would be unsafe, blood cultures, local aspiration of pus or radiologically guided biopsy may give valuable culture material prior to starting antibiotics (Summary box 40.5).

Summary box 40.5

Treatment of osteomyelitis

- Septic shock needs treatment without delay with antibiotics chosen empirically
- Otherwise the start of antibiotics should be delayed until specimens have been taken
- In elective surgery for osteomyelitis antibiotics should be stopped 2 weeks in advance

Local guidelines should be followed, but in general hospitals recommend a 'community acquired' level of cover using agents such as co-amoxiclav. Antibiotics to cover resistant Gram-positive organisms (e.g. vancomycin for MRSA) are considered if there has been prior hospital exposure, and antibiotics to cover resistant Gram-negatives (e.g. meropenem for *Pseudomonas*) are considered in settings such as severe diabetic foot infection. Prolonged intravenous antibiotic courses (i.e. 4–6 weeks of treatment) are usually recommended for bone infection, but there is little evidence to support this (Summary box 40.6).

Summary box 40.6

Antibiotics in osteomyelitis

- Follow local guidelines
- Amoxiclav is good for community-acquired infections
- Vancomycin is better for hospital-acquired MRSA
- Meropenem may be needed for *Pseudomonas*

NATIVE JOINT SEPTIC ARTHRITIS

Epidemiology

Bacterial infection of native joints occurs at an estimated incidence of 4–10 per 100 000 population per year in Western Europe, with higher rates in association with socioeconomic deprivation and in developing countries. The condition most characteristically affects patients at extremes of age, and in the context of an underlying joint abnormality or immunocompromise (see Summary box 40.7).

Summary box 40.7

Risk factors for septic arthritis

- Extremes of age
- Underlying joint abnormality, especially rheumatoid arthritis
- Immunocompromise (e.g. diabetes mellitus, HIV infection, immunosuppressive therapy)
- Joint instrumentation (e.g. steroid injection, arthroscopy)
- Intravenous drug abuse
- Indwelling central venous catheter
- Bacteraemia (especially *Staphylococcus aureus*)

Clinical features

Most patients present with an acute or subacute history of a single hot, swollen, painful joint. The joint is held immobile in the 'position of comfort', and there is severe pain if any attempt is made to move the affected joint actively or passively. In children and adults, the knee joint is most frequently affected; in neonates, the hip. Fever and other systemic signs are usually present, but their absence does not rule out the diagnosis, especially in adults where there may be no fever or only a low grade one.

Diagnosis

Aspiration and/or biopsy of intra-articular fluid or tissue will allow a Gram stain to be performed (although this is positive in only about one-third of infected cases), and then culture of a causative organism (positive in 80–90 per cent). However, results are delayed by the time taken to grow and identify the organism in the laboratory. The number of white cells seen is not diagnostic of sepsis, and crystals may be seen in infected joints as well as gout or pseudo-gout. The delay in obtaining a positive culture result, and the limited sensitivity and specificity of direct microscopy and Gram stain, should not delay early treatment for the infection. The decision to perform a surgical washout and give antibiotics should be based on the clinical picture (Summary box 40.8).

Summary box 40.8

Presentation of septic arthritis

- Children may be toxic and febrile but adults may only have a low-grade fever
- The joint is swollen and held in a characteristic position of comfort
- Any movement causes extreme pain

Management

Medical management

Antibiotics are usually given for 3–6 weeks (of which the first 2 weeks are commonly given intravenously).

Surgical management

Medical treatment alone is rarely indicated in joint sepsis. Prompt surgical drainage is a priority in order to avoid further damage to the joint (Figure 40.4a,b). In general, open washout is preferred to arthroscopic washout, depending on the joint involved. Chronic sepsis may lead to destruction of the joint and

Figure 40.4 (a) Septic arthritis of the hip in an intravenous drug user. This was untreated for several weeks resulting in destruction of the joint surface. (b) The same hip after nine months without treatment. The proximal femur and acetabulum have been grossly eroded by infection.

excision arthroplasty may be required. Subsequent joint replacement or fusion should only be considered when the infection has been completely cleared (Summary box 40.9).

IMPLANT-RELATED INFECTION

Epidemiology

The incidence of prosthetic joint infection in the UK is now <1 per cent per joint per year, with hips at slightly higher risk than knees. These rates appear to have fallen with improved operative practice and the recent introduction of surgical 'care bundles'. Risk factors include obesity, skin disease, comorbidity, prolonged or complicated surgery, revision surgery, fracture and postoperative wound infections.

Infection may follow internal fixation in up to 25 per cent of open tibial fractures.

Summary box 40.9

Native joint septic arthritis

- Most common at extremes of age, in patients with rheumatoid arthritis, and in association with immunocompromise
- Most commonly affects hips in neonates, and knees in adults and children
- Commonest pathogen is *Staphylococcus aureus*
- Joints should be aspirated for microbiology before starting antibiotics
- Management is prompt joint washout, followed by 3–6 weeks of antibiotics
- Gram stains are poorly predictive of infection and should not delay surgery.

Clinical features

Prosthetic joint infection may present with a discharging wound, cellulitis, pain, inflammation and swelling. Late infections are more likely to present with an indolent clinical syndrome of joint discomfort or mechanical dysfunction ('start-up' symptoms are particularly characteristic), with or without a discharging sinus. These presentations have led some to classify prosthetic joint infection into early (<3 months after implantation), intermediate (3–12 months) or chronic (>12 months).

Diagnosis

Plain radiographs may show features of loosening of a chronically infected prosthesis, and ultrasound may identify associated collections.

Multiple surgical specimens should be sent for culture (see 'General principles: diagnosis'), and it is most convenient to obtain these at the time of revision surgery or open debridement (Summary box 40.10).

Summary box 40.10

Implant-related septic arthritis

- The incidence in good units after joint replacement is now below 1 per cent
- Incidence after internal fixation of open tibial fractures remains as high as 25 per cent
- Late infection may present with low-grade symptoms (grumbling pain and start-up stiffness)
- X-rays may show lucency around the implant
- Multiple specimens need to be taken at surgery for reliable diagnosis

Management

A multidisciplinary approach is required, including orthopaedics, plastic surgery, infectious diseases, associated healthcare professionals, and, not least, the patient's understanding and views regarding their condition.

The choice of management strategy can be categorised as:

- salvage of an infected implant or
- removal of the infected implant with or without reimplantation.

Some groups have used the timing of presentation to determine this (i.e. salvage for early infection, but removal and revision for late infection). Others regard any firmly fixed implant as potentially salvageable, irrespective of the timing (and there are now several case series suggesting that this is feasible). However, it is agreed that loose infected implants should always be removed (Figure 40.5a,b). Furthermore, it is essential to achieve soft-tissue cover of bone and prosthetic material. This may be difficult around the knee, requiring local muscle flaps and the involvement of a plastic surgical team.

Management options can be divided into the following broad approaches:

- Debridement, antibiotics and implant retention (DAIR): can only be undertaken if the prosthesis is well-fixed. The surrounding infected soft tissue and bone must be fully excised and modular components exchanged. This cannot be achieved by arthroscopic surgery. Good soft-tissue cover is essential. Following debridement, the patient is treated with long-term antibiotics (frequently 6 weeks of intravenous therapy followed by six months or more of oral suppression).
- Two-stage joint revision surgery: a thorough excision is undertaken and all cement and loose foreign material is removed. An antibiotic-impregnated spacer may be implanted (which may be articulating). This is a temporary measure and cannot withstand full weight-bearing. The patient is treated with oral or intravenous antibiotics, most commonly for 6 weeks. A new prosthesis is implanted after the course of antibiotics has been completed. Re-revision surgery for infection has a higher failure rate than a first revision, and so early referral to a specialist centre should be considered.
- Single-stage joint revision surgery: the procedure is the same as above, but removal and reimplantation are undertaken in

the same operating session. Some centres consider single-stage revisions when less florid signs of infection are present (i.e. absence of collections or sinus tracts), or for frail patients for whom the risk of a second operation is higher. There are no trial data comparing outcomes with the two-stage approach.

- Joint removal or fusion: for patients who have intolerable symptoms (either pain, or profuse discharge), but for whom the surgical strategies outlined above are technically not possible or are ruled out by comorbid conditions, removal of the prosthesis without reimplantation may palliate symptoms. An example is the Girdlestone hip arthroplasty. Amputation may be necessary for knee or ankle implants.
- Suppressive therapy with antibiotics: in patients who are not medically fit for any operative intervention, or who choose to decline all surgical options, long-term treatment with antibiotics may help to suppress the symptoms of infection. There are limited data, but anecdotally the success rate of this approach seems low (Summary box 40.11).

Summary box 40.11

Prosthetic joint infection

- Well-fixed prostheses may be debrided and retained
- Loose prostheses must be removed
- Replacement can be made at the initial surgery (one stage) or after a delay to allow infection to be eradicated with a course of antibiotics (two stage)
- Multiple surgical samples are crucial for identifying a pathogen
- Thorough excision of infected tissue is a key determinant of outcome
- Long-term antibiotics may be used for patients who are not suitable for major revision surgery

Figure 40.5 (a) Sinus draining from the scar over the lateral side of the hip. This patient had a total hip replacement 14 years before which had been complicated by a wound haematoma and infection. (b) X-ray of both hips of the same patient. Both hips are loose but only the right side has definite infection.

INFECTION FOLLOWING FRACTURE FIXATION

Many of the principles outlined above can be applied to infections associated with metalwork used to fix fractures. Strategies which retain well-fixed implants need to achieve fracture union, at which point removal of the metalwork simplifies managing the infection. A course of oral antibiotics is unlikely to eradicate infection, but may allow fracture healing. The infection can then be addressed with implant removal.

If there is doubt about fracture stability, the implant should be removed and an external fixator applied after excision of the infected tissue. These cases may produce major reconstructive challenges (Figure 40.6a–d).

ACUTE OSTEOMYELITIS

This presents like septic arthritis with a short history of pain, limb swelling, loss of function and systemic upset. In young children, a fever and refusal to weight-bear may be the only clues.

Diagnosis

In the early phase (2–3 days), x-rays may be normal but MRI will show bone oedema and periosteal elevation. After 5–7

days, plain x-ray may show subtle abnormality with osteopenia and periosteal new bone formation. WCC and CRP are often abnormal in the early phase. Treatment should not be delayed pending investigations.

Management

Acute osteomyelitis can be treated with antibiotics alone, when the diagnosis is made within 2–3 days of onset of symptoms, there is no dead bone on imaging and there is no adjacent septic arthritis. Blood cultures are taken and high-dose intravenous antibiotics, active against *Staphylococcus aureus*, *Streptococci* and Gram-negative rods such as *Escherichia coli* are given. Cephalosporins, co-amoxiclav or a combination of flucloxacillin and gentamicin may be used.

The limb should be splinted and good analgesia given. Intravenous antibiotics are usually converted to oral therapy after cultures and continued for at least 4 weeks.

If the patient does not respond rapidly, the limb deteriorates or there is imaging evidence of progression of disease, surgery is indicated to prevent bone destruction and the onset of chronic osteomyelitis.

With prompt treatment, acute bone infection has a good prognosis with a 90 per cent cure rate. Failure to treat adequately produces chronicity, with recurrent infection over many years. In

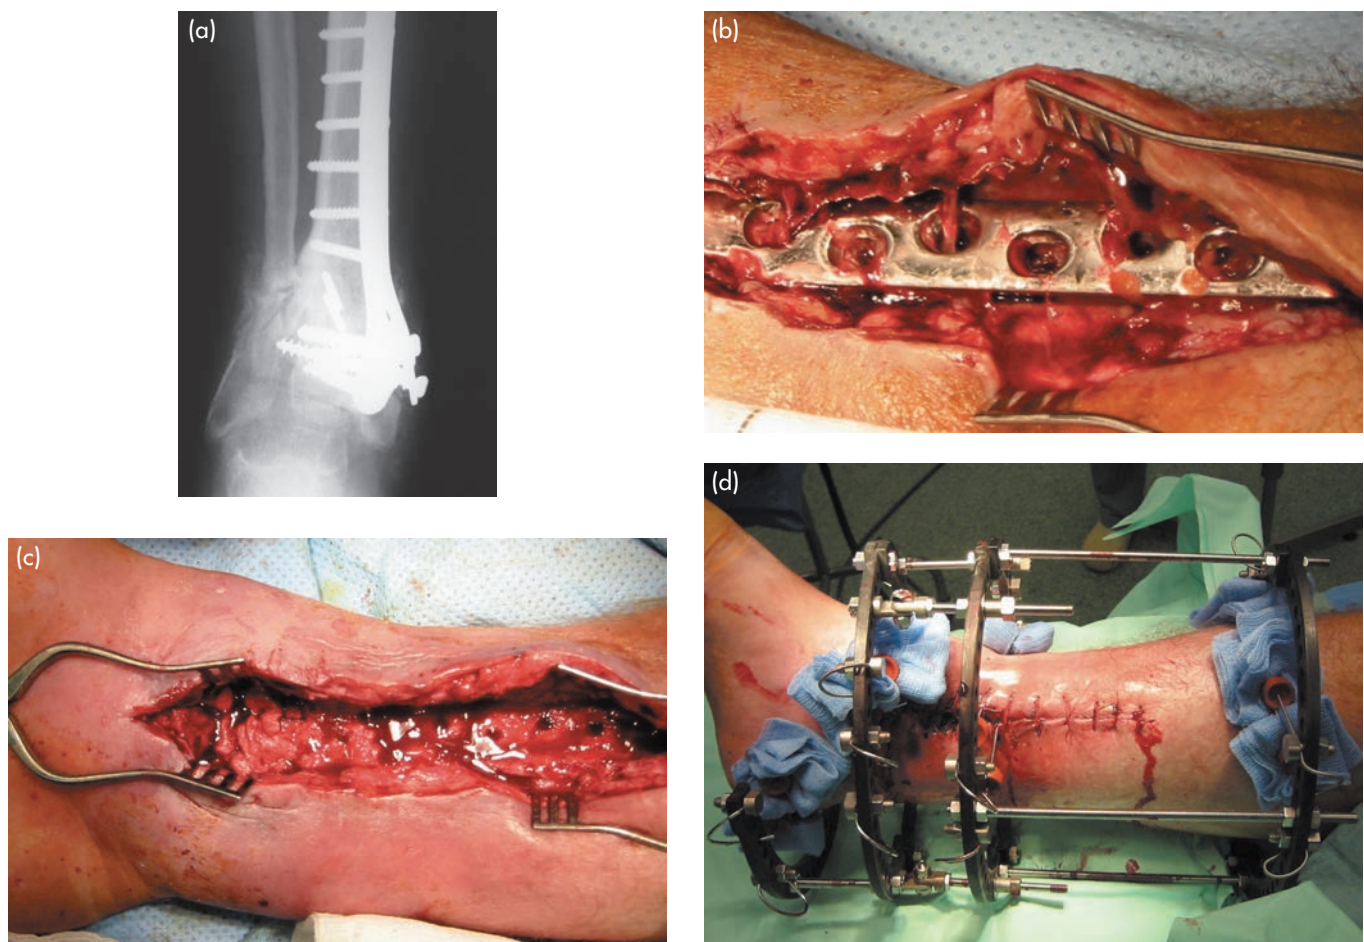

Figure 40.6 (a) X-ray of a complex distal tibia fracture which was internally fixed but complicated by deep infection. (b) At operation, the plate was loose and grossly infected. (c) The plate and all infected tissue was excised. The defect at the lower end was filled with an absorbable collagen antibiotic carrier. (d) The bone was stabilised with an Ilizarov circular external fixator.

children, the adjacent growth plates and joints may be affected with subsequent deformity and joint destruction (Summary box 40.12).

Summary box 40.12

Acute osteomyelitis

- Presents in children with toxæmia, fever and unwillingness to move the limb
- X-rays are normal for up to 1 week so are of no value in making an early diagnosis
- WBC and CRP are usually raised
- Early diagnosis is treated with high-dose i.v. antibiotics
- Late diagnosis and failure of medical treatment requires surgical debridement

CHRONIC OSTEOMYELITIS

This is a serious condition which may affect the patient for decades. It often occurs in those with multiple comorbidities which must be managed with the infection. Chronic bone infection is best treated within a dedicated multidisciplinary team.

Diagnosis

Plain x-rays can delineate soft-tissue swelling, subperiosteal reaction, bone destruction and sequestra. CT scans are good for cortical bone imaging and for planning surgical excision. MRI is the imaging test of choice. It can be adversely affected by metal implants and can overestimate the extent of infection when there is widespread reactive oedema. Blood tests are often normal in chronic osteomyelitis.

Management

The Cierny and Mader classification helps to define the features of the infection in the bone (four stages) and to relate this to the general condition of the patient. Patients can be divided into three physiologic 'host types' (A, no concurrent disease; B, compromised host; C, severe comorbidity preventing surgery). The interaction between the patient health status and the extent of the bone infection has been shown to be prognostic in outcome after surgery.

Stage 1 (medullary)

Only cancellous bone is involved. Excision of the dead bone can be carried out by intramedullary reaming or by windowing the cortex. The resulting defect may be filled with antibiotic-loaded cement beads or absorbable pellets. Structural stability is rarely affected.

Stage 2 (superficial)

Only the cortical bone is involved and this requires excision. It often follows skin ulceration and there may be large skin defects which require complete excision and local or free muscle flaps. If more than one-third of the cortical circumference is excised,

splintage is essential, usually with external fixation to prevent fracture. Secondary bone grafting may be needed.

Stage 3 (localized)

There is a limited area of dead cortical bone with medullary infection. Radical excision is required, and filling the defect and providing soft-tissue cover may be a challenge. Staged reconstruction may be necessary with cancellous bone grafting (Figure 40.7).

Figure 40.7 This large ulcer had been present for 30 years with underlying stage 3 chronic osteomyelitis. Biopsy of the skin edge revealed a squamous cell carcinoma; a rare complication of a long-standing sinus (Marjolin's ulcer).

Stage 4 (diffuse)

This involves the entire circumference of the bone and surrounding soft tissue. All infected non-unions are stage 4. Resection must be segmental and stabilisation in an external fixator will be required. Reconstruction will involve the introduction of new bone and healthy soft tissue. The Ilizarov method, which uses distraction osteogenesis to fill bone defects, is a powerful and successful technique. It can be combined with free tissue transfer. This allows reconstruction to proceed in parallel with rehabilitation.

After surgery, patients should be given antibiotics. In total segmental excision of infection, a short course may be indicated but in most chronic infections, 6–12 weeks is often advised. In infected fractures, antibiotics should continue until fracture union (Summary box 40.13).

DIABETIC FOOT INFECTION

The incidence of foot complications among patients with diabetes is 1–2 per cent per year, due to the combined influence of vascular insufficiency, mechanical disruption, peripheral and autonomic neuropathy and impaired tissue healing. Ulceration of the calcaneum and bones of the forefoot, especially the great toe and first metatarsal head, is common, leading to deep extension and osteomyelitis (Figure 40.8).

George Cierny III, contemporary, Medical Director, Department of Hyperbaric Medicine, St Joseph's Hospital, Atlanta, Georgia, USA.

Jon T Mader, 1944–2002, formerly Department of the Marine Biomedical Institute, Division of Infectious Diseases, The University of Texas Medical Branch, Galveston, USA. Cierny and Mader described the classification in: Cierny G, Mader JT, Pennick JJ. A clinical staging for adult osteomyelitis. *Contemp Orthop* 1985; 10: 17–37.

Gavril Abramovich Ilizarov, 1921–1992, pioneered this approach in Siberia in the 1950s in the management of osteomyelitis, fractures and limb deformities.

Figure 40.8 A severe diabetic foot infection, with marked infection, necrosis and soft-tissue loss. The patient was neuropathic but not ischaemic and it was possible to salvage a functional foot by 'filleting' the hallux and using the soft tissues to cover the defect.

Summary box 40.13

Osteomyelitis

- Acute infection must be treated rapidly to prevent morbidity
- Haematogenous infection most commonly affects long bones in children and the spine in adults
- MRI gives the best assessment of acute and chronic disease
- Chronic disease requires specialist surgery with excision, stabilisation and reconstruction
- Following surgery, antibiotic therapy is typically continued for 6 weeks

MRI is the most sensitive imaging modality for diagnosis of bone involvement. In severe infections antibiotic therapy should be guided by the results of culture of bone or tissue samples obtained surgically or radiologically. However, limited disease has a good prognosis, and in the absence of risk factors for resistant organisms (including prior treatment), empiric treatment can be justified.

Surgical debridement is required for collections, necrotic areas or more extensive osteomyelitis. Thought should be given to distinguishing superficial osteitis (stage 2 disease) resulting from loss of soft tissue cover (often in association with vascular compromise) from more extensive bone involvement. In the former, biopsy and antibiotic therapy may be of limited importance and

improving vascular sufficiency and relieving pressure with appropriate footwear much more important. Vascular compromise should be considered a relative contraindication to a surgical approach, and amputation may not be an easy option as wound healing will be poor (Summary box 40.14).

Summary box 40.14

Diabetic foot infection

- The most important risk factor for osteomyelitis is the presence of a foot ulcer
- Bone biopsy for culture is the criterion standard for assessment, but may not be necessary in mild disease
- In severe disease, surgical debridement of collections and/or necrotic tissue is required, followed by antibiotics tailored according to culture results

MUSCULOSKELETAL INFECTION CAUSED BY MYCOBACTERIA

Tuberculous arthritis/osteomyelitis had become uncommon in the UK, but remains prevalent in the developing world. There is now a resurgence in the developed world as a consequence of immigration, immunocompromise and drug addiction. The usual organism is *Mycobacterium tuberculosis*. Around half of all cases affect the spine, typically manifesting as paradiscal infection but also causing discitis and vertebral osteomyelitis. Native joint infection typically presents with monoarticular pain in a weight-bearing joint. Surgery may be crucial to facilitate synovial biopsy for diagnosis by culture and histopathology, as well as to decompress the spinal cord and debride infected tissue. When the mycobacteria are sensitive to antimicrobials the prognosis for microbiological cure is good.

CHAPTER
41Paediatric
orthopaedics

LEARNING OBJECTIVES

To be familiar with:

- Normal and abnormal development of the musculoskeletal system
- Normal variants versus pathological deformity
- Diagnosis and treatment of developmental hip dysplasia
- Presentation and management of other childhood hip conditions
- Management of clubfoot
- Problems associated with musculoskeletal infection in childhood

INTRODUCTION

Immature skeletons heal rapidly and can remodel with growth but physal injury or muscle imbalance can lead to progressive deformity. The conservative treatment of common conditions, such as developmental dysplasia of the hip (DDH) combines the child's remodelling ability with an understanding of the Heuter–Volkman principle and Wolff's law (Summary box 41.1): improving the biomechanical environment reverses abnormal growth. In contrast, in conditions such as Blount's disease, growth plate damage leads to asymmetrical growth and deformity. Advances in genetics and molecular science may improve our understanding of certain conditions and suggest new avenues of treatment.

Summary box 41.1

Laws governing the remodelling of bone

Heuter–Volkman principle

- Compressive forces inhibit growth
- Tensile forces stimulate growth

Wolff's law

- Bone deposition and resorption depends on the stresses applied

Three intercoordinated signalling centres control limb development. The apical ectodermal ridge (AER) guides mesodermal differentiation in a proximal-to-distal direction and controls digit formation. The zone of polarising activity (ZPA) directs anteroposterior limb development via the sonic hedgehog protein. The Wnt signalling centre develops dorsoventral axis configuration and limb alignment.

Certain limb anomalies are directly related to alterations in these centres. In experiments it is found that removal of the AER leads to a truncated limb, similar to a congenital amputation, and prevents interdigital necrosis. This results in syndactyly.

An error during fetal limb development may disturb the formation of other organs. Thus some limb anomalies are associated with systemic disorders which may be life-threatening (Summary box 41.2).

Summary box 41.2

Development of the musculoskeletal system

- Occurs 4–8 weeks after fertilisation
- AER controls proximal-to-distal differentiation and interdigital necrosis
- ZPA directs posterior-to-anterior differentiation
- Wnt influences dorsal-to-ventral differentiation

DEVELOPMENT OF THE
MUSCULOSKELETAL SYSTEM

The upper limb bud forms on the lateral wall of the embryo 4 weeks after fertilisation, followed promptly by the lower limb bud. By two months' gestation, differentiation of the limb elements is complete. Most congenital limb anomalies arise during this second month.

NORMAL VARIANTS

There are common normal variants which cause parental concern. These are intoeing, bowlegs, knock-knees and flatfeet: if they are symmetrical, symptom-free and supple, they require no intervention. There is often a family history of similar complaints. If the child fails to achieve their developmental milestones or there are functional problems, further investigation and help may be required.

Richard von Volkman, 1830–1889, Professor of Surgery, Halle, Germany.

Julius Wolff, 1836–1902, Professor of Orthopaedic Surgery, Berlin, Germany.

Walter Putnam Blount, 1900–1992, Professor of Orthopaedic Surgery, Marquette University, Milwaukee, WI, USA, described this condition in 1937.

Figure 41.1 Foot progression angle: a positive angle is caused by an out-toeing gait, a negative angle by an in-toeing gait.

Intoeing gait

Intoeing is defined as a negative foot progression angle. It can result from one or more lower limb torsional anomalies (Figure 41.1 and Table 41.1).

Persistent femoral anteversion presents clinically with excessive internal rotation at the hip joint. All femurs are anteverted at birth but spontaneous correction occurs because as the femur lengthens it also rotates. If by 12–13 years a significant deformity persists associated with functional difficulties, corrective osteotomy may be justified. Compensatory external tibial torsion may develop.

Internal tibial torsion is assessed by the foot/thigh angle and is commonly associated with physiological tibia vara in infants. Spontaneous correction can be expected by age 4, as the tibia also rotates as it grows.

Metatarsus varus is usually flexible; spontaneous correction occurs in 90 per cent of children by the age of 2–4 years. For the more rigid foot, stretching, corrective plasters or straight-last shoes may help. Surgical release is rarely indicated.

Table 41.1 Common sites and causes of intoeing gait in childhood.

Site	Cause
Femur/hip	Persistent femoral neck anteversion
Tibia	Internal tibial torsion
Foot	Metatarsus varus

Other abnormalities of gait

Toe-walking is a phase in normal gait development. If the gait does not mature to a heel-toe pattern by the age of three

Figure 41.2 Graph to show the normal tendency of limb alignment to change from varus to valgus with growth.

years, physiotherapy may help, and older children benefit from surgical lengthening of contracted gastrocnemius complexes. If toe-walking starts after walking age, a spinal or neuromuscular aetiology such as a tethered cord or a muscular dystrophy must be considered.

Out-toeing is less common than intoeing but may result from relative femoral retroversion, external tibial torsion or flexible flat feet. The young child may be late walking because of poor balance associated with the foot posture. This condition improves with growth/time.

Knock-knees and bowlegs

Normal children's leg shape changes dramatically over time. All children start life with bowlegs, often accompanied by tibial torsion. By the age of 2–3 years they have developed knock-knees, which regress towards the normal adult tibiofemoral angle of 7° valgus by the age of 7 (Figure 41.2).

Traditionally, the intercondylar or intermalleolar distance is used to quantify the deformity, rather than measuring the angle. This is not very accurate. Further investigation is needed when the deformity is severe, asymmetrical or symptomatic. The most common pathological causes are previous trauma, rickets or a skeletal dysplasia.

Flat foot

Before development of the medial longitudinal arch, all children (<3 years) have flat feet. Only 15 per cent of adults have flat feet so the natural history is for improvement, influenced by both familial and racial factors.

The painless, flexible flat foot needs no treatment. Orthoses do not alter the natural history but can alleviate symptoms if they arise. All flat feet have a flattened medial arch with a valgus heel but the two major types should be distinguished from each other (Table 41.2).

The symptomatic, rigid flat foot is usually the result of a tarsal coalition or inflammation and requires appropriate medical or surgical treatment (Figure 41.3) (Summary box 41.3).

Figure 41.3 Oblique radiograph of the foot that shows the most common form of tarsal coalition, a calcaneonavicular bar.

Table 41.2 Flat feet.

Types	Characteristics
Flexible	On tiptoe the arch is restored and the heel corrects into varus; subtalar joint movements are full and pain free
Rigid	On tiptoe the arch fails to return; subtalar joint movements are restricted and often painful

Summary box 41.3

Normal variants

- Intoeing or outtoeing may be caused by excessive foot deformity, tibial or femoral torsion
- Neurological abnormalities must be excluded in toe walkers
- Children's legs are often bowed until age 2 and then knock-kneed until age 6 or 7
- Flexible, pain-free flat feet do not need treatment

Postural abnormalities

Many babies are subjected to moulding pressures *in utero*. At birth they have 'postural abnormalities' such as torticollis, calcaneovalgus feet and plagiocephaly, which improve with time and stretching exercises.

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES OF THE SKELETON

Although many skeletal abnormalities are identified antenatally or at birth, others only become apparent with growth. Skeletal disorders are often linked to soft-tissue abnormalities; the presence of a skin dimple or the presence of a vascular malformation should be a warning sign (see Table 41.3).

Many anomalies require little treatment and cause minimal functional disability whereas others, such as proximal femoral focal deficiency and radial club hand, pose considerable challenges. In these cases the functional and cosmetic needs of the child and family must be balanced against available resources and expertise. Despite advances in limb reconstruction techniques, there is little high quality evidence-based data from skeletally mature patients to support their widespread use. In the

meantime, considerable advances are occurring with amputation prosthetics.

Table 41.3 Classification of congenital limb malformations.

Category	Example
Failure of formation of parts	
Transverse	Congenital amputation
Longitudinal	Fibular hemimelia
Failure of differentiation	Vertebral body fusion; syndactyly
Duplication	Extra digits
Overgrowth	Gigantism; macrodactyly
Undergrowth	
Congenital constriction band syndrome	Often affects hands/feet with poor formation of the digits
Generalised skeletal abnormalities	Skeletal dysplasia, e.g. achondroplasia

Generalised skeletal dysplasias

Achondroplasia

Achondroplasia is caused by a defect in the *FGFR3* (fibroblast growth factor receptor 3) gene that affects enchondral bone formation. Patients present with a disproportionate short stature (disproportionate means that the limbs are shorter than the trunk) and classic clinical and radiographic features (Figure 41.4). Underdevelopment of the foramen magnum and spinal stenosis can cause neurological difficulties. Correction of limb alignment may be necessary and limb lengthening techniques are used in some countries.

Hereditary multiple exostoses – diaphyseal aclasis

Exostoses grow as the child grows and may cause cosmetic or functional difficulties that justify excision. Differential growth between the paired bones of the lower arm and leg can lead to joint deformity, exacerbated by the physeal distortion secondary to altered mechanical forces. Such growth abnormalities are predictable and treatment is designed to prevent deformity from developing (Figure 41.5).

Enchondromas

Abnormal ossification of the physeal cartilage columns may be the precursor of these cartilaginous masses, and can be seen on x-ray because they are ossified (see Chapter 39).

Fibrous dysplasia

This common disorder is often a chance finding on x-ray and probably results from a somatic mutation causing defective bone formation, see also Chapter 39 (Figure 41.6 and Summary box 41.4).

METABOLIC BONE DISEASE

Rickets

In all types of rickets, the primary problem is inadequate

Summary box 41.4**Congenital and developmental abnormalities of the skeleton**

- Achondroplasia affects endochondral ossification and presents with disproportionate dwarfism
- Exostoses may cause cosmetic or functional problems
- Patients with Ollier's disease (multiple enchondromatosis) often have lesions in the hand and feet

Figure 41.4 Achondroplasia. (a) Clinical photograph of a child with achondroplasia. (b) X-ray of the lower limb of a child with achondroplasia showing short limbs, widened metaphyses and a varus deformity of the distal tibia.

Figure 41.5 X-ray of the knee showing multiple broad-based osteochondromas.

mineralisation of growing bone (Table 41.4). In severe cases, skeletal deformities, with classic radiographic features, affect every physis (Figure 41.7). Medical treatment improves mineralisation. Correction of the deformity then occurs with growth. Surgery may be necessary for the management of pathological fractures or to correct mechanical misalignment once the medical condition has been controlled.

Table 41.4 Common causes of rickets.

Nutritional	Reduced intake of vitamin D and calcium
Environmental	Inadequate exposure to sunlight
Gastrointestinal disease	Crohn's disease, gluten-sensitive enteropathy
Genetic	X-linked hypophosphataemia
Renal disease	End-stage renal failure, renal tubular anomalies
	Secondary hyperparathyroidism changes may be present

Osteogenesis imperfecta (brittle bone disease)

Osteogenesis imperfecta (OI) represents a spectrum of conditions linked by a qualitative and/or quantitative malfunction of collagen production. Many specific genetic defects have been identified; most caused by mutations in the collagen genes. The bone may break easily but it heals promptly and well. All structures that contain collagen may be affected. This accounts for the ligamentous laxity, blue sclerae and poor teeth found in some phenotypes.

Cyclical bisphosphonate treatment decreases bone resorption and bone turnover. This reduces bone pain and the fracture rate, which in turn improves weight-bearing mobility and bone strength (Figure 41.8).

Figure 41.6 The diaphyseal lesions of fibrous dysplasia classically have a 'ground glass' appearance and, if extensive, may be associated with angular deformity or pathological fracture.

Figure 41.7 X-rays, which are characteristic of rickets, show widened physes with cupped, flared metaphyses.

Following fracture, care must be taken to minimise disuse osteoporosis and to maintain bone alignment. Treatment options range from simple casting techniques to more specialised surgical procedures to correct/maintain limb alignment while allowing growth (Figure 41.9 and Summary box 41.5).

ABNORMALITIES OF THE HIP

Developmental dysplasia of the hip

DDH defines the spectrum of hip instability ranging from the hip that is in joint but has a shallow (dysplastic) acetabulum and may be 'pushed out' (Barlow positive) to the dislocated hip that is irreducible (Ortolani negative). These tests are described below. The associated clinical picture varies with the pathology and the age at presentation: neonatal hips may be unstable, a toddler may limp, adolescents may experience exercise-induced

Figure 41.8 X-ray of a child with osteogenesis imperfecta who has been treated with cyclical bisphosphonates. Multiple growth lines are visible in addition to an intramedullary device.

Figure 41.9 X-ray of two adolescent femora showing different types of intramedullary alignment device *in situ*.

Summary box 41.5

Metabolic bone disease

- Rickets from nutritional or other causes, is characterised by failure of bone mineralisation
- In OI there is defective type I collagen production
- In severe forms of OI, frequent fractures lead to progressive deformity: Bisphosphonate treatment may reduce the fracture rate

pain and an adult may have pain secondary to degenerative arthritis.

Incidence

The incidence of neonatal instability is 1–2:1000 live births whereas that of true dislocation is ~2:1000 live births, many hips stabilise spontaneously.

Aetiology of DDH

- Gender: DDH is five times more common in girls than boys, possibly related to hormonal factors causing temporary joint laxity.
- Breech presentation: DDH is present in ≤ 20 per cent of breech babies, particularly with the extended breech position.
- Birth order: DDH is more common in firstborns and in the left hip because of the common fetal position in a tight primigravid uterus where movement is restricted.
- Oligohydramnios: Restricts fetal movement. The presence of other postural deformities (torticollis and metatarsus adductus) raises the possibility of DDH.
- Family history: A positive family history significantly increases the risk of DDH. This may reflect faulty acetabular development or excessive ligamentous laxity.

DDH is often found in association with generalised syndromes or neuromuscular conditions. These teratologic hips are usually resistant to surgical intervention and the child's overall condition and prognosis must be considered when planning treatment.

Diagnosis

Neonates

Clinical assessment

All neonates are screened for limitation of hip abduction and instability. The hips are examined again at 6 weeks. The knees and hips are flexed and the thigh held by the examiner with the thumb along the medial aspect and a finger behind the greater trochanter. The hips are abducted gently: if abduction is limited, the hip may be dislocated. The examiner's finger then lifts the greater trochanter upwards; a soft clunk – the Ortolani test – with improved hip abduction, signifies hip reduction (Figure 41.10a). If the hip does abduct fully, then the leg is adducted while downward pressure is applied to the knee with the examiner's thumb and palm: an unstable hip may dislocate or sublux – the Barlow test (Figure 41.10b). With an irreducible hip there is no clunk of reduction but there will be limitation of abduction. Bilateral dislocation may be missed as abduction is symmetrical and abduction may be normal when there is ligamentous laxity.

Ultrasound assessment

Ultrasonography defines the anatomy and the stability of the hip joint. It is used to monitor early treatment (Figure 41.11) or as a screening tool (universally or just for 'at risk' patients). Ideally, screening scans should be performed between 4 and 6 weeks of age and, when necessary, treatment started promptly. It should not be forgotten that the sonographic appearances of most hips improve (become less dysplastic) spontaneously as the child grows. X-rays are used to evaluate dysplasia from four to five months of age, but are of limited value in the newborn because no ossific nucleus is visible so the position of the hip cannot be seen. The appearance of the femoral ossific nucleus is also often delayed in DDH (Figure 41.12).

Infants

Hip checks, looking for limitation of abduction in flexion and limb shortening, are part of routine developmental monitoring.

Figure 41.10 Line diagram illustrating the Ortolani (a) and Barlow (b) tests for developmental dysplasia of the hip.

Child

Children present with a limp and sometimes with unilateral tiptoeing because the affected leg is short. It is also externally rotated. Abduction in flexion is limited and there may be an extra thigh crease. The signs may be subtle and easily missed in an unsteady toddler. If both hips are affected there will be a waddling gait and a lumbar lordosis.

Adolescent/adult

Discomfort after exercise is common but the pain may be in the knee. X-rays show dysplasia, subluxation or degenerative change (Summary box 41.6).

Summary box 41.6

Diagnosis of DDH

- All neonates are screened clinically (Barlow and Ortolani tests), at birth and at 6 weeks
- Ultrasound is used to monitor hip stability/anatomy and as a screening test in 'at-risk' babies
- X-ray is useful from four months onwards
- Older children present with a limp or tiptoe walking

Management

When diagnosed early, conservative treatment is usually successful, but after walking age surgery is required. The objective is to obtain a stable, congruous reduction of the femoral head into the acetabulum while avoiding damage to the capital epiphysis (avascular necrosis) or to the growth plate which causes stiffness, coxa vara and shortening.

Neonate

Due to ligamentous laxity, some normal hips are unstable initially. Most stabilise within the first few weeks of life and do not need treatment.

Hips that remain unstable or are dislocated at rest are treated with harnesses or splints that maintain hip reduction in the position of abduction and flexion. Most harnesses (Figure 41.13) allow controlled movement while splints hold the hips more rigidly and so may carry a greater risk of avascular necrosis. If

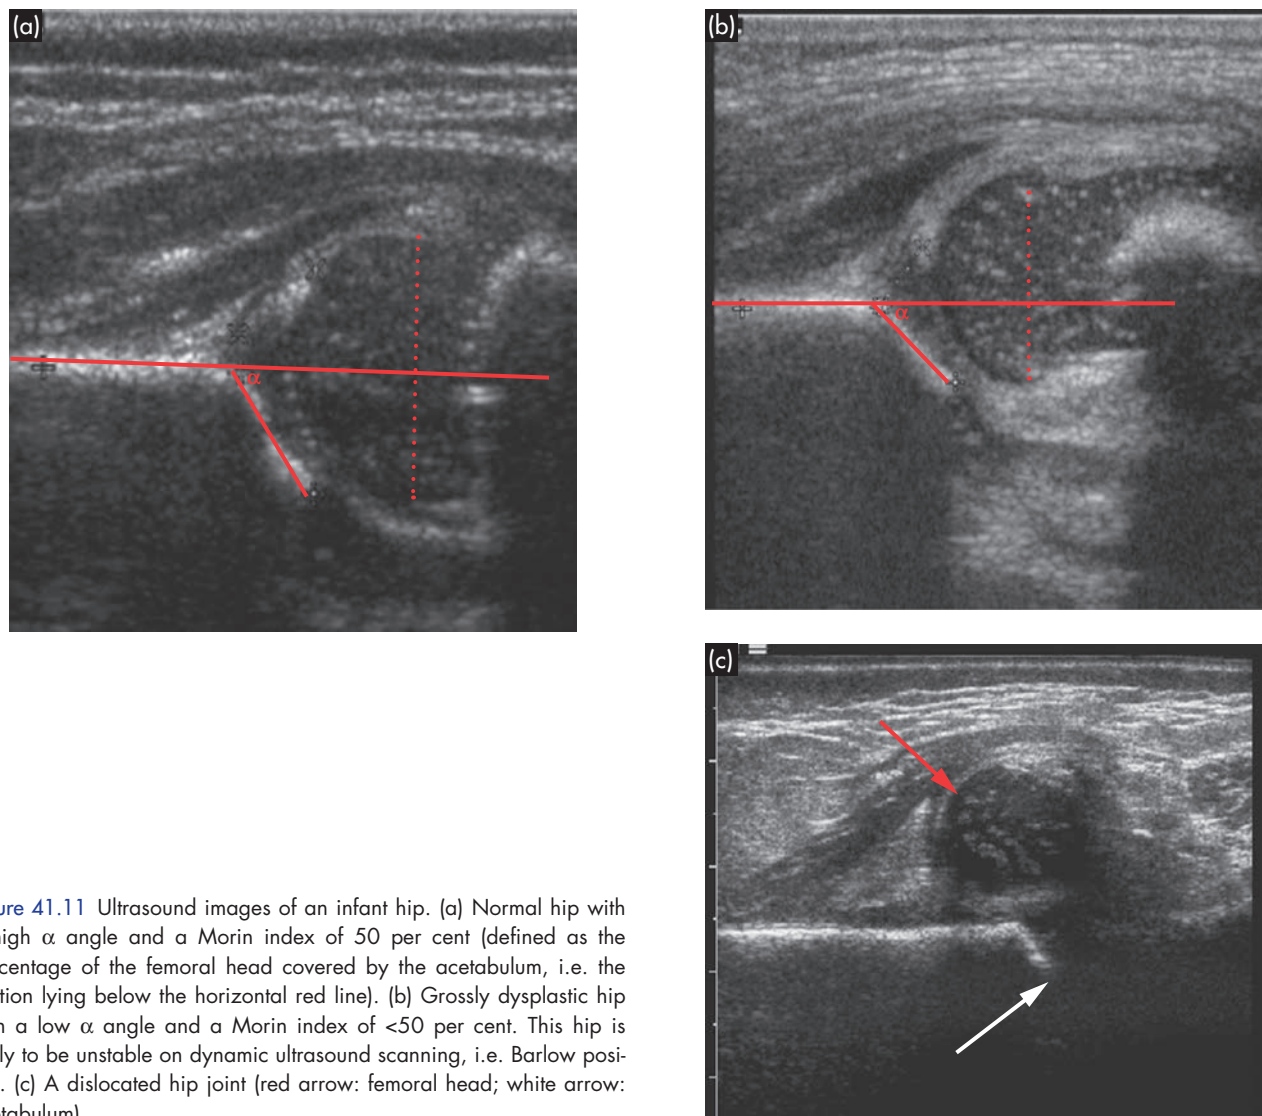

Figure 41.11 Ultrasound images of an infant hip. (a) Normal hip with a high α angle and a Morin index of 50 per cent (defined as the percentage of the femoral head covered by the acetabulum, i.e. the portion lying below the horizontal red line). (b) Grossly dysplastic hip with a low α angle and a Morin index of <50 per cent. This hip is likely to be unstable on dynamic ultrasound scanning, i.e. Barlow positive. (c) A dislocated hip joint (red arrow: femoral head; white arrow: acetabulum).

Figure 41.12 Anteroposterior pelvic x-ray showing Hilgenreiner's line (a) and Perkins' line (b). The femoral head (ossific nucleus) of a normal hip lies in the inner lower quadrant. The right hip is normal, the left hip has developmental dysplasia of the hip.

the hips fail to relocate or stabilise then non-operative treatment should be discontinued.

Infant

Successful treatment using a harness is unusual after the age of 4–6 months. For the late-presenting hip or the hip that fails conservative treatment, an examination under anaesthetic may result in a closed reduction. The arthrogram shows whether a concentric reduction is present and, if not, it will indicate which structures are blocking reduction. Apsoas/adductor release can be performed as necessary. A closed reduction will need to be held reduced with a hip spica cast for several months.

If the hip is irreducible or can only be held reduced in an extreme position with a small safe zone, then treatment must be abandoned and an open reduction considered via a medial or anterior approach (Summary box 41.7).

Toddler and young child

The older the child, the less likely it is that reduction by closed methods will succeed (Figure 41.14). The traditional approach is then to carry out open reduction via an anterior approach

Figure 41.13 The anterior strap of the Pavlik harness controls hip flexion whereas the posterior strap limits adduction and encourages abduction.

Summary box 41.7

Management of early DDH

- Many hips that are unstable in the first few days of life do not need treatment
- Up to 4–6 months, a harness or splint is effective treatment
- In older babies, closed reduction is sometimes possible
- For failed closed treatment, open surgical reduction is required

around the age of 9–12 months. A pelvic osteotomy may be required to reorientate or close down the acetabulum and femoral shortening or derotation osteotomies are often required to improve stability. Earlier surgery via the medial approach can be considered but no additional surgery, such as capsulorrhaphy or bony realignment can be performed through that incision.

Older child

In the older child a similar approach is necessary but pelvic and femoral realignment will always be needed, and the results tend to be less rewarding. Surgery is often avoided in children over the age of 6–8 years in bilateral cases and the age of 8–10 in unilateral cases.

Adolescent and young adult

These hips are often subluxed rather than truly dislocated. On investigation, the hip may be reducible and the joint can be recreated with a combination of pelvic and femoral osteotomies. For the irreducible hip, acetabular augmentation may reduce symptoms and delay the onset of degenerative change (Summary box 41.8).

Figure 41.14 Anteroposterior pelvic x-ray showing acetabular dysplasia with subluxation (developmental dysplasia of the hip) of the left hip. This child presented at the age of 4.

Summary box 41.8

Management of late-presenting DDH

- The older the child, the more likely it is that they will need surgery
- Femoral osteotomy can stabilise the hip and reduce pressure on the femoral head
- Pelvic osteotomy redirects or reshapes the acetabulum
- Acetabular remodelling decreases after the age of 3–4 years
- Avascular necrosis is a risk of DDH treatment

Secondary procedures and complications

Regular follow up ensures that the hip development is monitored. Acetabular remodelling may be assessed objectively by measuring the acetabular index or the centre-edge angle (Figure 41.15).

If the acetabulum does not improve, a variety of pelvic osteotomies can be considered. Avascular necrosis (AVN) with overgrowth of the greater trochanter can cause a Trendelenburg limp and distal transfer of the trochanter may help. Occasionally, a leg length difference needs treatment. There is also an increased risk of osteoarthritis which may need arthroplasty later in life.

Legg-Calvé-Perthes' disease

Incidence and aetiology

This rare condition, characterised by the development of AVN of the proximal femoral epiphysis, affects boys predominantly between the ages of 4 and 8 years. Ten per cent develop bilateral disease. Although the aetiology is unclear, several factors have been implicated (Summary box 41.9). There are also other causes of AVN of the femoral head (Summary box 41.10).

Figure 41.15 Anteroposterior pelvic radiographs demonstrating the acetabular index (AI) and the centre-edge (CE) angle. (a) Normal hips; (b) the left hip shows residual dysplasia. The AI is increased compared with the normal right hip. The left CE angle would be smaller than the right too but it has not been measured on this x-ray.

Summary box 41.9

Factors implicated in the pathogenesis of Perthes' disease

- Low birthweight
- High birth order
- Delayed bone age
- Low socioeconomic status

Summary box 41.10

Causes of avascular necrosis of the femoral head

- Steroids
- Infection
- Perthes' disease
- Sickle cell disease
- Hypothyroidism
- Skeletal dysplasia – classically multiple epiphyseal dysplasia

Pathology

Once established the process follows a well-described course. The avascular change may affect all or part of the femoral head. The avascular bone may collapse. This is followed by fragmentation of the ossific nucleus and subsequent revascularisation and regeneration ('healing') of the bony epiphysis; in this respect Perthes' disease is a self-limiting condition but, during the collapse and fragmentation phases, femoral head deformity occurs. This is not reversible and has a permanent effect on the health of the hip joint.

Diagnosis

The history, clinical examination and anteroposterior and 'frog' lateral x-rays of the pelvis make the diagnosis. An intermittently painful hip (or knee) with a limp and restriction of hip movements requires investigation. The x-ray features vary with the disease stage and may not correlate with the clinical condition (Figure 41.16). MRI can be helpful.

AVN of the femoral head may be due to other causes and a differential diagnosis should be considered, particularly when changes are bilateral.

Management

Treatment aims to minimise femoral head deformity, and thus the likelihood of secondary acetabular dysplasia. This is achieved by maintaining a good range of joint movement, with some restriction in activity level, and using analgesia and physiotherapy as required. The routine use of crutches and/or wheelchairs are discouraged because they promote a flexion/adduction posture. Recent evidence suggests that brace management on its own does not alter the natural history of the condition.

The role of operative treatment is controversial. Surgery can be performed early to prevent deformity secondary to femoral head collapse or late to 'salvage' a poor mechanical situation when deformity is limiting movement (Table 41.5). Joint distraction (arthrodiastasis) may preserve joint movement and maintain femoral head height but has not gained popularity.

Not all hips with deformity require 'salvage' surgery: young children, with more time to remodel, have a better prognosis as the secondary acetabular changes result in an aspherical but congruent joint. Long-term follow up may be required to deal with mechanical symptoms caused by loose osteochondral fragments, a Trendelenburg gait secondary to trochanteric overgrowth or a short-leg gait. Degenerative change may occur in adult life.

Other conditions (all eponymous) also show x-ray changes of AVN (Table 41.6).

Arthur Thornton Legg, 1874–1939, orthopaedic surgeon, The Children's Hospital, Boston, MA, USA.

Jacques Calvé, 1875–1927, orthopaedic surgeon, La Fondation Franco-Américaine, Berck Plage, Pas-de-Calais, France.

Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tübingen, Germany.

Legg, Calvé and Perthes all described osteochondritis of the head of the femur independently in 1910.

Table 41.5 A guide to some of the surgical options available for the management of Perthes' disease.

Timing	Type of procedure	Comments	Aim
Early	Femoral osteotomy Innominate osteotomy Shelf acetabuloplasty	Varus and derotation	To cover ('contain') the vulnerable femoral head
Intermediate	Arthrodiastasis	Hinged distraction to allow movement	To reduce deforming pressures on the femoral head
Late	Femoral osteotomy Cheilectomy Arthrotomy Trochanteric epiphyseodesis	Valgus and extension To remove osteochondral fragments	To improve joint congruity and hence function; to improve joint mechanics
Contralateral limb	Distal femoral epiphyseodesis		To improve leg length discrepancy and reduce effects on hip joint mechanics

Again, the x-ray changes 'heal' but the change in shape of the affected bone may lead to secondary joint stiffness and loss of function (Summary box 41.11).

Figure 41.16 Anteroposterior pelvic x-rays of Perthes' disease demonstrating whole head involvement. (a) Right-sided disease; the process is in an early phase. The area of dense necrotic bone is visible (b). There has been collapse and fragmentation.

Summary box 41.11

Legg-Calvé-Perthes' disease

- Most common in boys aged 4–8 years
- AVN leads to femoral head collapse, healing occurs with the return of the blood supply
- Management aims to maintain femoral head sphericity
- Treatment may be non-surgical (to maximise range of movement) or surgical (for containment or 'salvage')
- The prognosis is better in younger children who have more remodelling potential

Table 41.6 Other conditions (commonly classified as osteochondroses) in which the x-ray appearance is of avascular necrosis.

Condition	Affected bone
Keinbock's disease	Lunate
Panner's disease	Capitellum of the humerus
Freiberg's disease	Metatarsal head – usually the second
Köhler's disease	Navicular

Slip of the upper (capital) femoral epiphysis

The physis connects the proximal femoral epiphysis (the femoral head) to the metaphysis (femoral neck). In certain physiological or pathological conditions a 'stress fracture' through the physis allows the epiphysis to displace as it would with an intracapsular femoral neck fracture, so the leg lies short and externally rotated. There is painful limitation of hip movement. Hilton's law, which states that a joint is supplied by the same nerves as the muscles that move the joint, explains why many children present with knee pain although the pathology is in the hip.

Incidence and aetiology

Slip of the upper (capital) femoral epiphysis (SUFE or SCFE) is rare with an incidence of ~5:100 000 population. Boys are

affected most commonly: the peak incidence is related to the start of puberty, hence it is earlier in girls. As a result of growth stimulated by hormonal changes, the strength of the growth plate, its resistance to shear and its orientation are reduced. The hip is therefore 'at risk' and normal forces, exacerbated by obesity and repetitive minor trauma, precipitate a slip. Other conditions, such as hypothyroidism, renal failure and previous radiotherapy treatment (local or to the pituitary region) also increase the risk.

Diagnosis

The diagnosis is suggested by the history and examination and confirmed on plain x-ray (Figure 41.17). Displacement is often more obvious on a lateral view. Indeed it can easily be missed by the unwary clinician if only the anteroposterior (AP) view is checked.

Classification

Slip severity can be graded on the lateral x-ray (Table 41.7) or classified according to the onset of symptoms: acute, chronic or acute-on-chronic.

Table 41.7 Grading of the severity of slip of the upper (capital) femoral epiphysis.

Slip severity	Metaphysis uncovered (%)
Mild	<33
Moderate	33–66
Severe	>66

Management

Following an acute episode the patient is often unable to weight-bear and the slip is considered to be unstable by the Loder classification. Displacement is often moderate or severe. This situation is essentially equivalent to a displaced intracapsular femoral neck fracture. This means that an acute unstable SUFE is an emergency. The AVN risk is considerable but is reduced by prompt screw fixation that stabilises the 'fracture' (Figure 41.18). Gentle repositioning of the femoral head often occurs inadvertently with the reduction of muscle spasm that accompanies the anaesthetic. To be effective such treatment must take place within 24 hours of injury. If delayed, the AVN rate increases.

With chronic slips the patient is usually able to weight-bear, albeit with pain, and the slip is considered stable. Screw or pin fixation *in situ* relieves pain and often improves the range of movement but a permanent restriction of movement will be present with limitation of flexion, internal rotation and adduction (Figure 41.19). The leg will also always be slightly short.

In the acute-on-chronic case, repositioning of the acute element of the slip may be feasible. In the severe slip it may be impossible to place a screw in a satisfactory position in the epiphysis, even by starting anteriorly on the neck. In addition, once healed, there may be significant, persistent deformity leading to restriction of joint movement. In these cases a realignment osteotomy may be considered. As with all osteotomies, the closer the correction is to the site of deformity, the better the outcome; however, in this situation, the risks of AVN or chondrolysis may

Figure 41.17 Anteroposterior pelvic x-ray demonstrating a mild slip of the upper (capital) femoral epiphysis on the right side. A line drawn along the upper margin of the femoral neck should transect the femoral head (left side) – if it does not do so (right side) a slip is present. There are many other x-ray features that help confirm the diagnosis but the changes are often subtle.

Figure 41.18 Anteroposterior pelvic x-ray showing a left-sided acute severe unstable slip of the upper (capital) femoral epiphysis. (a) At presentation; (b) following partial repositioning and fixation with a cannulated screw.

John Hilton, 1805–1878, surgeon, Guy's Hospital, London, UK.
Randall Loder, Professor of Orthopaedic Surgery, Philadelphia, PA, USA.

be unacceptably high, and so an intertrochanteric osteotomy could be considered. Bilateral slips do occur and prophylactic pinning of the normal but 'at-risk' hip may be indicated (Summary box 41.12).

Summary box 41.12

Slip of the upper (capital) femoral epiphysis

- Occurs in prepubertal children, mainly boys
- Often presents with knee pain and the leg may be short and externally rotated
- Classification may be according to the severity of slip, whether acute or chronic, or whether stable or unstable – all affect the prognosis
- Most slips are pinned *in situ* with a single screw into the centre of the epiphysis
- Avascular necrosis is the most feared complication of both the condition and its treatment

Figure 41.19 Anteroposterior x-ray showing screw fixation *in situ* of a case of bilateral chronic slip of the upper (capital) femoral epiphysis. Note the position of the screw entry point on the anterior femoral neck.

ABNORMALITIES OF THE KNEE AND LOWER LEG

Many knee problems are self-limiting. Others require surgical consideration to reduce the risk of later degenerative change.

Osteochondritis dissecans

Osteochondritis dissecans (OCD) most commonly affects the knee. An osteochondral fragment becomes partially or completely separated from the joint surface. Magnetic resonance imaging (MRI) is the best way of showing the lesion. In mild cases, or those treated early with rest and activity modification, the osteochondral fragment may remain attached and heal. If it detaches, partially or completely, mechanical symptoms necessitate treatment either to encourage bone healing via fixation of the fragment or to remove a loose body. Younger children have a better prognosis.

Discoid meniscus

This invariably affects the lateral meniscus which is abnormally thick and covers most of the tibial plateau. The child presents with a painful clunk on knee extension. MRI is usually diagnostic. Surgery is indicated for relief of pain or mechanical symptoms.

Anterior knee pain

In adolescents the extensor mechanism of the knee is a common site of knee pain.

Osgood–Schlatter disease is a traction apophysitis of the patellar tendon insertion. Pain, tenderness and swelling at the tibial tubercle, exacerbated by exercise, are diagnostic and x-rays are unnecessary. Treatment is relative rest and analgesia and the condition resolves once the apophysis has fused.

Patellofemoral pain is common and often attributed to a degree of patellar maltracking. As for patellar instability, treatment starts with physiotherapy to develop the quadriceps muscles, and to correct any wasting which may have occurred as a result of the pain. There are a multitude of operations described to improve the 'postulated mal-tracking', but as is so often the case in surgery when there is a large choice of operations, none work reliably and so surgery is rarely appropriate.

Fibular hemimelia

In fibula hemimelia there is a congenital failure of formation of the lateral 'column' of the lower leg (Figure 41.20 and Table 41.8).

Management is tailored to the severity of the deficiency. Treatment options range from a shoe raise, through multiple episodes of limb equalisation surgery to amputation for the worst cases. An early prediction of the leg length discrepancy at maturity allows a realistic treatment plan to be devised for the patient.

Table 41.8 Classical x-ray features of fibula hemimelia.

Foot and ankle	Absent lateral rays; tarsal coalition; ball and socket ankle joint
Lower leg	Absent or deficient fibula; tibial bow
Knee	Absent cruciate ligaments; deficient lateral femoral condyle
Femur	Relative hypoplasia
Limb length and alignment	Short; external rotation \pm valgus

Blount's disease

The aetiology of this disordered growth in the posteromedial proximal tibial physis is unknown. The infantile form is more common in Afro-Caribbeans but the adolescent-onset disease affects all ethnic origins. The child presents with progressive and often severe tibia vara with significant intoeing. The x-ray features are diagnostic (Figure 41.21).

Treatment is surgical: following correction of limb alignment via an osteotomy, an epiphyseodesis of the remaining physis may be necessary to prevent recurrence with subsequent limb length equalisation surgery as required.

Robert Bailey Osgood, 1873–1956, Professor of Orthopaedic Surgery, Harvard University Medical School, Boston, MA, USA.

Carl Schlatter, 1864–1934, Professor of Surgery, Zurich, Switzerland.

Osgood and Schlatter described osteochondritis of the tibial tubercle independently in 1903.

Figure 41.20 Anteroposterior (a) and lateral (b) x-rays of two lower limbs showing some of the features of a fibular hemimelia: absent fifth ray in the foot, absent fibula and deformed tibia.

Congenital pseudarthrosis of the tibia

This rare condition presents clinically with an anterolateral bow of the tibia with or without a fracture. Classic x-ray changes are noted and 50 per cent are associated with neurofibromatosis. Once fractured, the tibia is reluctant to heal. Long-term orthotic treatment may be necessary, with subsequent surgical procedures designed to obtain bony union and restore leg length (Summary box 41.13).

Summary box 41.13

Abnormalities of the knee and lower leg

- Osteochondritis dissecans – better prognosis in children than adults
- Discoid meniscus – usually lateral, may require surgery
- Anterior knee pain – treatment almost always conservative
- Fibular hemimelia – associated with abnormalities from the foot proximally (foot worse than hip)
- Blount’s disease – clinically, a sharp proximal tibial angulation
- Congenital pseudarthrosis of the tibia – anterolateral bowing

Figure 41.21 Anteroposterior x-ray of the left knee demonstrating changes compatible with Blount’s disease affecting the posteromedial tibial physis with changes in both the epiphysis and the metaphysis.

ABNORMALITIES OF THE FOOT AND ANKLE

Parents are often concerned that minor foot abnormalities will cause their child to be clumsy or slow. This is rarely the case, so reassurance is a cornerstone in the management of abnormalities of the foot and ankle in children.

Congenital talipes equinovarus (the ‘clubfoot’)

The clubfoot is deformed in three planes (Figure 41.22). In true congenital talipes equinovarus (CTEV) the deformity is fixed. Intrauterine moulding can cause an identical pattern of deformity that is postural and therefore correctable.

Incidence and aetiology

The reported incidence varies from one to six cases per 1000 live births, depending on racial differences. It is more common in boys and bilateral in approximately 50 per cent of cases. A family history is common but inheritance is multifactorial. Most cases are idiopathic but the outcome varies with the aetiology so it is important to consider the cause when planning treatment (Table 41.9).

Table 41.9 Several different types of clubfoot are recognised.

Type	Example
Postural	
Idiopathic	
Neuromuscular	Spina bifida; arthrogryposis; spinal cord anomalies – considered in feet that resist treatment or relapse
Syndromic	Trisomy 15

Pathology

The talonavicular joint is subluxed with the navicular displaced medially with respect to a deformed talar head and

Figure 41.22 Anteroposterior photograph of a foot showing the classic deformities associated with a clubfoot. The hindfoot is in equinus and varus, there is midfoot cavus and the forefoot lies adducted and apparently supinated, although actually pronated relative to the hindfoot.

neck. Ligaments, particularly the calcaneofibular ligament, and tendon sheaths, such as the posterior tibial tendon sheath, are shortened and thickened and contain contractile myofibroblasts. The gastrocnemius and posterior tibial muscles are smaller than normal, with reduced myofibrils and increased connective tissue, possibly because of a local neuromuscular abnormality. The vascular supply via the dorsalis pedis may be diminished. It remains unclear which abnormalities are primary and which occur as the deformity develops.

Clinical assessment

It should be possible to distinguish the postural clubfoot from the structural (rigid) foot soon after birth.

The postural clubfoot may require physiotherapy with stretching or casting, but can soon be manipulated into a 'normal' position of 45° of abduction and full dorsiflexion with the calcaneus well down in the heel pad. Medial creases are minimal and posterior creases shallow and multiple.

The structural clubfoot has fixed deformity with elements of equinus, varus and supination and cannot be corrected beyond neutral. Cavus is often marked. The heel feels 'empty' as the calcaneus is held up by the shortened tendo Achilles. There is a deep medial and single posterior crease.

All children with structural clubfoot deformity have a small calf and foot and some tibial shortening. Children should be examined carefully for neurological signs of intraspinal pathology.

Both Pirani and Dimeglio have developed scoring systems based on foot appearance in the position of maximal correction which predict treatment response and progress (Summary box 41.14).

Family counselling

The diagnosis of CTEV may be made during an antenatal ultrasound: counselling is limited by uncertainty as to the severity of the problem but the parents can be reassured that their child will walk, run and play with his/her peers.

Summary box 41.14

Clubfoot

- Multiplanar deformity: hindfoot equinus and varus, forefoot adduction and supination with a plantarflexed first ray
- Incidence is 1–6:1000 live births, more common in boys and with a familial tendency
- Most cases are idiopathic but neuromuscular causes include spina bifida and arthrogryposis
- Scoring systems (Pirani/Dimeglio) are used to assess the severity

Treatment

Ponseti method

The method described by Ponseti corrects foot deformity in 95 per cent of cases without the need for a formal surgical release. The technique has been introduced successfully worldwide. Treatment commences within a few days of birth. A specific series of manoeuvres, followed by a series of well-moulded above-knee plaster casts results in gradual correction of the deformity (Figure 41.23). The head of the talus is the fulcrum around

Figure 41.23 A photograph of a series of casts documenting the step-wise correction of the foot deformity with the Ponseti method of serial manipulation and casting.

which the rest of the foot swivels. After the forefoot has been corrected, most feet (about 80 per cent) require a percutaneous Achilles tenotomy in order to dorsiflex the foot satisfactorily.

Once corrected, the foot position is maintained by a foot abduction orthosis (FAO) that holds the foot in external rotation and slight dorsiflexion. The FAO is worn full-time for three months and at 'night and nap-time' for up to four years. Poor compliance with the FAO is associated with a higher relapse rate. Recurrent deformity can be treated with further plasters, but a tibialis anterior tendon transfer may be required around the age of 2.5–4 years for dynamic supination.

Feet treated with the Ponseti method are less stiff, less likely to be painful and less subject to overcorrection than those treated surgically. The Ponseti method is significantly better than other reported conservative regimes.

Surgical treatment

When conservative treatment fails, surgical intervention is required, ideally before walking age.

Surgical release is generally performed 'à la carte', with sequential release of the pathologically tight structures via either a Turco incision or the Cincinnati incision to reduce the subluxed joints (Table 41.10). Stabilisation may require the use of temporary Kirschner wires. Deformity correction should not be compromised by wound closure and the Cincinnati incision can be left to heal by secondary intention if necessary.

Postoperative casting is followed by splinting and physiotherapy as required. Good or excellent results are reported in 60–80 per cent of children treated surgically but stiffness and over- or undercorrection are common complications.

Surgery for residual or recurrent deformity is often difficult and requires a careful assessment of the forefoot, hindfoot and tibial torsion. Surgical procedures may involve further soft-tissue releases or tendon transfers but, in the presence of fixed deformity, bony correction is often necessary. The foot becomes progressively stiffer with each surgical intervention (Summary box 41.15).

Other foot and ankle conditions

Most postural deformities such as metatarsus adductus and calca-neovalgus feet improve spontaneously.

Congenital vertical talus (CVT) is rare and often associated

Table 41.10 The four stages of a peritalar release that might be required for the correction of a severe clubfoot deformity.

Site	Structures requiring lengthening or release
Posterior	Tendo Achilles Ankle and subtalar joints Calcaneofibular ligament Posterior elements of the peroneal tendon sheaths
Medial	Abductor hallucis Tibialis posterior Talonavicular joint Toe flexors
Lateral	Calcaneocuboid joint
Plantar	Plantar ligaments Plantar fascia
Protect	Neurovascular bundle Talocalcaneal interosseous ligament (if possible)

Summary box 41.15

Treatment of clubfoot

- The Ponseti method of serial casting is successful in 95 per cent of feet, avoiding formal surgical release although percutaneous tenotomy is usually required
- The standard sequence is elevation of the first ray, gradual forefoot abduction to 60° and, finally, dorsiflexion, usually following Achilles tenotomy
- Tibialis anterior transfer can be used to correct dynamic supination in older children
- Surgical release may need to address posterior, medial, plantar and lateral structures, and will result in a stiffer foot than one treated conservatively

with neuromuscular conditions such as arthrogryposis and spinal dysraphism. Clinically, there is a stiff ‘rocker-bottom’ foot with dorsal dislocation of the navicular on the talus (Figure 41.24). Correction is surgical although a ‘reverse’ Ponseti method with a limited surgical approach is showing good early results.

In **tarsal coalition** there is failure of segmentation of adjacent tarsal bones. School-age children present with hindfoot pain and recurrent ankle sprains. The stiff subtalar joint cannot accommodate uneven ground. The most common coalitions are talocalcaneal and calcaneonavicular (see Figure 41.3). X-ray, computed tomography (CT) or MR may be required to confirm the diagnosis. Treatment is initially conservative but, if the coalition requires surgical excision, this should be carried out before significant degenerative changes develop.

Curly toes that are flexed and medially deviated are common, often familial and rarely need treatment. Strapping is ineffective. Flexor tenotomy is used when there are symptoms.

Other causes of foot pain in children include osteochondroses (see Table 41.6):

- Köhler’s disease: presents with dorsal forefoot pain and swelling in young children. The navicular appears to suffer a spontaneous avascular necrosis and collapses. The alarming radiological appearances resolve spontaneously and without sequelae.

Figure 41.24 Congenital vertical talus. (a) Lateral photograph demonstrating a ‘rocker-bottom foot’. (b) Lateral x-ray showing hindfoot equinus and suggesting dorsal subluxation of the non-ossified navicular and forefoot with respect to the head of the talus.

- Sever’s disease (enthesopathy of the calcaneal apophysis): presents with heel pain related to activity. Tightness in the calf muscle complex may be a contributing factor.
- Freiberg’s osteochondrosis: presents with forefoot pain and avascular change in the second metatarsal head. It may be asymptomatic and present as an incidental finding on x-ray. Symptomatic bony spurs and osteochondral fragments may need excision (Summary box 41.16).

Summary box 41.16

Other foot and ankle conditions

- Congenital vertical talus – presents as ‘rocker-bottom’ foot
- Tarsal coalition – presents as a stiff, painful flat foot
- Curly toes are common – most do not need treatment
- Osteochondroses - almost always self-limiting

ABNORMALITIES OF THE UPPER LIMB

Minor finger abnormalities are common (Table 41.11) and frequently require surgical intervention. Comfort and function are more important than appearance.

Function is also the most important consideration when managing more extensive upper limb abnormalities. Treatment

Alban Köhler, 1874–1947, radiologist of Wiesbaden, Germany, described this disease in 1908.
James Warren Sever, 1878–1964, orthopaedic surgeon, The Children’s Hospital, Boston, MA, USA, described apophysitis of the os calcis in 1912.
Albert Henry Freiberg, 1869–1940, Professor of Orthopaedic Surgery, The University of Cincinnati, Cincinnati, OH, USA, described this disease in 1926.

is delayed until hand dominance is established and it is clear what problems a specific deformity is causing a given child. Children are very adaptable and cope with disabilities much more readily than their parents/doctors expect.

Table 41.11 Common minor congenital anomalies affecting the hand.

Anomaly	Definition	Treatment
Extra/accessory digits		Excise/amputate when necessary
Syndactyly	Failure of separation of digits	Separation with/without skin grafting for functional or cosmetic reasons
Trigger thumb (digit)		Release of the A1 pulley of the flexor tendon sheath
Clinodactyly (usually the fifth digit)	Abnormal angulation of the digit in the radioulnar plane	Surgical treatment of the delta phalanx if deformity progressive or interfering with hand function
Camptodactyly (usually the fifth digit)	Fixed flexion deformity of proximal interphalangeal joint	Splinting/physiotherapy; surgery rarely indicated

Radial club hand

This longitudinal failure of formation is commonly associated with other malformations, for example as part of the VACTERL syndrome (abnormal vertebrae, anus, cardiovascular system, trachea, oesophagus, renal system and limb buds). The clinical problem depends, most specifically, on whether the thumb is present and functional (Figure 41.25). Treatment is a balance of conservative measures including physiotherapy and splinting, and judicious surgery to centralise and stabilise the hand and

Figure 41.25 Anteroposterior x-ray of a radial club hand demonstrating a short radius, a deformed ulna and an absent thumb.

wrist on the single bone forearm. Thumb reconstruction may be technically challenging. In later childhood, forearm lengthening may be considered.

Radioulnar synostosis

Failure of proximal separation of the embryonic radius and ulna means that the forearm cannot pronate and supinate. The hand is in a fixed position and the child presents if this results in a functional problem. Osteotomy of the forearm bones can change the fixed position (from pronation to neutral) but does not restore movement.

Congenital radial head dislocation

The dislocation is usually posterolateral compared with the classic traumatic anterior dislocation (Figure 41.26). Some restriction of elbow joint movement and forearm rotation is noted along with discomfort on activity. Radial head excision may be required (Summary box 41.17).

Figure 41.26 Radial head dislocation. (a) Lateral x-ray of a forearm showing a proximal radioulnar synostosis with a congenital posterolateral dislocation of the radial head. Note the underdeveloped radial head and neck and compare with. (b) Lateral x-ray of a traumatic anterior dislocation of the radial head with a normal appearance to the head and neck and a deformity in the proximal ulna.

Summary box 41.17

Upper limb abnormalities

- Radial club hand is frequently associated with other congenital anomalies, for example the VACTERL or Holt–Oram syndromes
- Radioulnar synostosis presents with a fixed forearm position in childhood
- Congenital radial head dislocation is usually posterolateral

SPINAL DEFORMITIES AND BACK PAIN

Congenital deformities

Congenital vertebral deformities are either failures of formation (a hemivertebra) or of segmentation (unilateral or bilateral fusions or bars). The clinical result is usually a scoliosis (Figure 41.27). Treatment should be based on the potential for curve progression. When a kyphosis develops, progressive neurological deficit is common. Bracing is ineffective for congenital vertebral deformities.

Scoliosis

The term ‘scoliosis’ describes spinal deformity in three planes: lateral curvature is the most obvious deformity while the rotational component is most apparent in forward flexion when the rib asymmetry creates a ‘rib hump’ (Figure 41.28). The cause may be idiopathic, neuromuscular, syndrome-related or congenital. Both the aetiology and the age of onset affect the natural history (Table 41.12). In general, the earlier the onset, the more likely the deformity is to be progressive.

The adolescent idiopathic curve is the most common, affecting girls more than boys. Idiopathic scoliosis is generally not painful and so in the presence of significant pain, tumour and infection must be excluded. The Cobb angle is a radiological measurement that defines severity and helps to guide treatment (Figure 41.29). Curves $<20^\circ$ do not need treatment, progressive curves of $25\text{--}40^\circ$ may be braced, and those $>40^\circ$ are considered for surgery (Summary box 41.18).

Figure 41.27 Anteroposterior x-ray of the spine demonstrating multiple congenital vertebral anomalies including hemivertebrae.

Table 41.12 Classification of idiopathic scoliosis.

Type	Age of onset
Infantile	0–3 years
Juvenile	4–10 years
Adolescent	11–18 years
Adult	Onset at maturity

Summary box 41.18

Scoliosis

- Multiplanar deformity includes an unsightly rotational component
- Aetiology may be congenital (underlying bony malformation), neuromuscular, syndromic or idiopathic
- A leg length discrepancy causes a postural scoliosis
- Adolescent idiopathic scoliosis is the most common structural scoliosis
- Back pain associated with scoliosis may be due to infection or tumour
- Treatment depends on the severity and likelihood of curve progression – it varies from observation, through bracing, to surgery

Kyphosis

When a kyphosis exceeds the normal $20\text{--}50^\circ$, the cause may be postural or structural. Structural kyphosis is commonly secondary to Scheuermann’s disease, presenting as a progressive adolescent kyphosis characterised radiologically by $\geq 5^\circ$ vertebral wedging at three adjacent levels and end-plate changes. The aetiology is unknown. Treatment ranges from physiotherapy and bracing to surgery, depending on severity, progression and symptoms.

Spondylolisthesis

Spondylolysis defines a defect in the pars interarticularis of the vertebra. There are six types: congenital (dysplastic facet joints), isthmic (weak or elongated pars), degenerative, post-traumatic, pathological or post-surgical. Spondylolisthesis occurs when the upper vertebra slips forward on the lower; it is graded according

Figure 41.28 Clinical photograph of the Adam’s forward bend test that demonstrates the presence of a rib hump and the level of the curve.

Figure 41.29 Anteroposterior x-ray of a spine with a scoliosis (right thoracic), with a Cobb angle of 47°.

to the percentage slip, measured by relating the slipped vertebra to the one below (Table 41.13).

Mild slips are often asymptomatic and do not require treatment. Treatment (physiotherapy, bracing and surgery) depends on the degree of slip and symptoms; mechanical back pain may respond to conservative methods but neurological involvement usually requires surgical intervention.

Table 41.13 Classification of spondylolisthesis according to severity of the slip.

Grade	Percentage slip
0	No slip
1	<25%
2	26–50%
3	51–75%
4	>75%
Spondyloptosis	>100% – complete translation

Torticollis

In torticollis the head is tilted toward and rotated away from the tight sternocleidomastoid muscle.

Congenital torticollis is usually secondary to intrauterine moulding but may present with fixed sternocleidomastoid contracture or with a palpable ‘tumour’ within the muscle. There is a

strong correlation with DDH. Most cases resolve with stretching but persistent cases develop facial asymmetry and require surgical release of the sternocleidomastoid at one or both ends.

Acquired torticollis is less common and may be caused by gastro-oesophageal reflux, posterior fossa tumour/other regional abnormality, inflammation/infection, ocular problems or atlanto-axial rotatory subluxation.

Back pain

Children report back pain less frequently than adults although >50 per cent will have had an episode by late adolescence. Back pain in a child is a ‘red flag’ for serious spinal pathology but if mild, intermittent or occurring only on strenuous activity, it is usually self-limiting (Summary box 41.19).

Summary box 41.19

‘Red flag’ symptoms and signs for spinal pathology

- Systemic illness, fever or weight loss
- Progressive neurological deficit
- Unrelenting or night pain
- Spinal deformity

All these require urgent further investigation with a full blood count (FBC), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), plain x-ray and MRI or other appropriate imaging. Other causes of back pain include intra-abdominal, renal and systemic pathology, and all must be considered. Physiotherapy encourages symptomatic improvement (Summary box 41.20).

Summary box 41.20

Other spinal conditions

- Excessive kyphosis may be caused by Scheuermann’s disease
- Spondylolisthesis is forward slip of one vertebra on another; it may cause mechanical and, rarely, neurological symptoms
- Torticollis may be congenital and usually responds to stretching of the fibrosed sternocleidomastoid muscle. Acquired torticollis may be due to one of several significant pathologies
- Back pain with red flag symptoms and signs requires urgent investigation

NEUROMUSCULAR CONDITIONS

Joint stability and limb function rely on the complex integration of the musculoskeletal and neurological systems. Damage to either leads to one of several conditions linked only by the fact that they are incurable. Management is directed at helping the child cope with their disability, minimising further deterioration and maximising function. It is important to have an understanding of what the damage is and what the future holds.

Spina bifida and polio are classic lower motor neurone lesions whereas cerebral palsy and head injuries affect upper motor

neurons and the higher centres. There are often other disabilities such as blindness, epilepsy and intellectual difficulties to consider.

In children, even if the initial insult to the neuromuscular system is non-progressive, the effects of the insult change with growth. Damage at any level of the neuromuscular system leads to an alteration in tone and muscle imbalance associated with decreased control of movement. Abnormal muscle pull, particularly in combination with the effects of gravity, alters bone growth leading to deformity and joint contracture. Muscles are relatively weak and with body growth and a weight increase, they are no longer strong enough to control a heavier limb, particularly when deformity means they are working at a mechanical disadvantage.

A multidisciplinary approach to management is essential. Good physiotherapists and orthotists will reduce the need for surgical intervention and in the postoperative period they help ensure that the surgical benefits are maximised. In conditions such as Duchenne muscular dystrophy there is substantial evidence for the benefits of certain surgical procedures; however, in other conditions (cerebral palsy) there are fewer such long-term validated studies.

In general, it is important to maintain a full range of joint movement, muscle length and tendon excursion. This is easier to achieve in patients with a flaccid paralysis or low tone. The maintenance of muscle strength is also important. The use of splints, positioning techniques, seating and sleeping systems is common with the aim of preventing fixed contractures.

Surgery has a valuable role in the management of selected patients (Table 41.14).

The surgeon must understand that altering ankle posture may affect knee and hip posture/function and vice versa. The patient must have the intellectual ability and motivation to recover from the surgical procedure. Some of the factors which need to be considered in an holistic approach to the patient are given in Summary box 41.21 (see also Summary box 41.22).

Cerebral palsy

Cerebral palsy is caused by a non-progressive insult to the developing brain in the perinatal period; in most cases only risk factors, such as prematurity, rather than specific causes, such as hypoxia, can be identified. The effects of cerebral palsy may only become apparent as the child grows and fails to reach expected developmental milestones. At this stage investigations may help

Summary box 41.21

Factors to be considered in the assessment of a neuromuscular disability

- Is the insult to the neurological system progressive or non-progressive?
- Is it located centrally or peripherally?
- Is it general or focal?
- Is it associated with other abnormalities or not?

Summary box 41.22

Principles of treatment of neuromuscular conditions

- A neurological defect, whether progressive or not, may cause progressive deformity as the skeleton grows
- A multidisciplinary approach is essential
- Primary therapy aims to maintain range of movement and prevent fixed contractures with an emphasis on managing tone and position
- Surgery has a limited role in the management of neuromuscular conditions

with aetiology and may predict the pattern of the cerebral palsy: premature babies may show evidence of periventricular leucomalacia on a brain MRI, which is associated with the development of a spastic diplegia with relative preservation of intellectual function.

In general, the pattern of involvement can be classified according to the anatomical site involved and the effect on muscle tone (Table 41.15). The prognosis for walking can be predicted by identifying evidence of neurological development, i.e. the loss of primitive reflexes.

An important aspect of management is the control of high tone. Tone can be reduced with drugs such as diazepam and baclofen. Alternatively, neuromuscular blockers such as botulinum toxin can bring about a focal reduction in tone by preventing acetylcholine release at the neuromuscular junction. The effect is temporary, giving a 'window' during which the physiotherapists can stretch agonists and strengthen antagonists. It is important to

Table 41.14 General types of surgical procedure that might be considered in the management of a patient with a neuromuscular condition.

Surgical procedure	Aim of treatment
Lengthening of the muscle-tendon unit	Restore joint range (but results in relative muscle weakness)
Tendon transfer	Improve functional movement; rebalance muscle forces, after correction of fixed deformity
Release of joint contracture; correction of bony deformity	Restore mechanical alignment, and allow muscles to work in a more efficient manner
Fuse/stabilise/relocate joints	Improve posture/function Reduce pain
Neurological procedures, e.g. selective dorsal rhizotomy, intrathecal baclofen pumps	Reduce tone
Leg equalisation procedures	Improve lower limb mechanics

Guillaume Benjamin Amand Duchenne (Duchenne de Boulogne), 1806–1875, a neurologist who worked successively in Boulogne and Paris, France, but who never held a hospital appointment.

differentiate between dynamic and fixed contractures; the latter will not respond to tone management or splinting.

Table 41.15 Classification of cerebral palsy with respect to muscle tone and site of involvement.

Characteristics	
Tone	
Low	
High	
Mixed	Often low tone in trunk with high tone in the limbs
Variable	High tone and low tone apparent in the same limb on different occasions
Site	
Hemiplegia	Arm more affected than leg
Diplegia	Legs more affected than arms
Total body involvement	Often significant intellectual impairment

The classic cerebral palsy gait patterns demonstrate flexor spasticity. The child with spastic diplegia has problems at all levels of the lower limb. Single event multilevel surgery (SEMLS) is popular and gait analysis (both observational and computerised) contribute to the patient management planning. Computerised analysis provides objective evidence of joint movement and mechanics in multiple planes (Figure 41.30). Appropriate bone and soft-tissue procedures can then be planned. Botulinum toxin helps with postoperative pain and spasm.

In the child with total body involvement (TBI) and high muscle tone, hip subluxation and eventual dislocation are common but often asymptomatic (Figure 41.31). Current thinking is that symmetry and pelvic position are important so hips should be kept in joint by the simplest means possible with early surgical intervention if necessary. Aggressive management of a spinal deformity will initially concentrate on seating position and subsequently emphasise spinal bracing or surgery.

Overall, it is important to remember what the child's needs will be once they have reached adulthood. Independent mobility and an effective means of communication are two of the most important requirements. Hence, it may not be appropriate to invest time and effort into gaining an upright posture if mobility will be achieved via an electric wheelchair and a hand-controlled car (Summary box 41.23).

Summary box 41.23

Cerebral palsy

- Brain injury is non-progressive
- Classified as hemiplegia, diplegia or TBI
- Tone may be high, low or variable but there is generalised, relative muscle weakness
- In ambulant children, gait analysis may be used to plan surgery or botulinum toxin injections
- In TBI, primary concerns are hip subluxation and spinal deformity

Polio

Despite an effective polio vaccine, this disease still occurs. About 1–2 per cent of patients develop neurological problems when the virus affects the anterior horn cells. Muscle weakness is proportionate to the number of motor units destroyed. Patients often develop trick movements to cope with their muscle weakness and minor joint contractures might actually improve function. Careful assessment before surgery is essential and both the surgeon and the patient must understand the goals of treatment.

Spina bifida

The extent of the disability varies with the level of the lesion: upper motor neurone involvement will produce spasticity while the more classic lower motor neurone lesion will merely produce weakness. Hydrocephalus may contribute to the complexity of the situation. Muscle imbalance leads to secondary joint deformity but the often profound, accompanying sensory disturbance, may affect the choice of surgical and non-surgical options.

Muscular dystrophy

Many types of muscular dystrophy exist that vary in terms of severity and distribution of involvement. Surgical intervention aims to improve quality of life. This is best achieved by operating early to release joint contractures. This will help to maintain walking ability and good spinal posture.

Brachial plexopathy

The obstetric brachial plexus injury is still common with a devastating effect on upper limb function, particularly if antigravity motor activity has not recovered by six months. Neural repair may be necessary in the infant. Later surgical interventions aim to prevent joint contractures and improve function.

INFECTION

Worldwide, bone and joint infection remain frequent causes of significant morbidity.

Septic arthritis

Joint infection is usually secondary to haematogenous spread but direct inoculation does occur, for example during a neonatal venepuncture. Diagnosis can be difficult in the very young and in those presenting with overwhelming sepsis. Neonates, children with immunocompromise and those with sickle cell disease are at increased risk. At the other end of the spectrum, the differentiation between joint sepsis and transient synovitis of the hip can be difficult to make.

Classically, the child presents with pain, fever and a reluctance to use the joint; in the lower limb this implies a reluctance to weight-bear. On examination, local tenderness and painful restriction of movement are apparent and in superficial joints inflammation may be obvious, with joint swelling.

Investigations include FBC, ESR, CRP and blood cultures. Plain x-rays help to exclude other diagnoses and may identify osteomyelitis. Ultrasound scans of deep-seated joints, such as the hip, will identify joint effusions (Figure 41.32). Other investigations such as MRI may be useful but should not be regarded as a necessity: good clinical skills, regular patient review and a high index of suspicion are more valuable. Four clinical predictors can differentiate between septic arthritis and transient synovitis (Summary box 41.24 and Table 41.16).

Figure 41.30 Gait analysis graphs such as these demonstrate the normal range of joint movements (green band) at hip (a), knee (b) and ankle (c) during the stance and swing phases of gait. The abnormal joint ranges are shown in red (right leg) and blue (left leg) and demonstrate the excessive hip flexion and lack of knee extension and abnormal ankle function associated with the 'crouch' gait of a child with cerebral palsy.

Summary box 41.24

The clinical predictors of Kocher *et al.* for the diagnosis of a septic joint

- History of fever
- Non-weight-bearing
- Erythrocyte sedimentation rate >40 mm/h
- White cell count >12 × 10⁹ µL

Table 41.16 The value of the clinical predictors of Kocher *et al.* in determining the likelihood of the joint being septic.

No. of positive predictors	Predicted probability of joint sepsis
0	<0.2%
1	3.0%
2	40.0%
3	93.1%
4	99.6%

Pus in a joint is destructive: the proteases produced by leukocytes destroy both the collagen matrix of the articular cartilage and the bacteria. AVN may occur secondary to pressure effects or ischaemic infarction. The treatment of a presumed septic arthritis is thus the prompt removal of pus from the joint and appropriate adequate antibiotic therapy. Pain relief and rest are also important

Figure 41.31 Anteroposterior pelvic x-ray of a child with spastic cerebral palsy. Both hips are subluxed. Reimer's migration percentage ($a/a + b$ as a percentage) has been measured as approximately 60 per cent on the right hip.

as are the general health and nutrition of the patient. The joint is aspirated and if pus is confirmed then a formal washout is mandatory; standard teaching states that the joint must be opened, irrigated and free drainage encouraged via the capsulotomy. Recent literature supports repeated aspiration/irrigation via a large-bore cannula or a small arthroscope. Antibiotic usage is guided by the local hospital policy, the source of the infection, the Gram stain and, in due course, the culture and sensitivity of the organism identified. Joint instability, particularly in the hip joint (Figure 41.33a), may require the joint to be splinted in the reduced position while the inflammatory process settles.

The most frequently identified organism is *Staphylococcus aureus*. Streptococcal infection is also common and other organisms are more prevalent in certain age groups, e.g. the neonate, in certain conditions such as sickle cell disease, or in certain countries. The *Haemophilus influenzae* type B (Hib) vaccine has essentially eliminated *Haemophilus influenzae* as a cause of infection.

Improvement is judged clinically and by monitoring the inflammatory markers. Reaccumulation of pus does occur and must be suspected and treated promptly if the child fails to improve (Summary box 41.25).

Summary box 41.25

Septic arthritis

- Diagnosis is difficult in neonates and the immunocompromised
- Typical presentation is pain, fever and a reluctance to move the joint or weight-bear
- Investigations should include FBC, ESR, CRP, blood cultures and appropriate imaging studies, combined with astute clinical skills
- Pus in a joint can destroy articular cartilage and cause avascular necrosis
- Treatment is prompt removal of pus, appropriate antibiotic therapy, pain relief and splintage

Figure 41.32 Ultrasound scan of a hip joint. A large effusion is distending the joint capsule. The dotted line represents the distance between the femoral neck and the joint capsule.

Osteomyelitis

As with septic arthritis, bone infection is usually caused by haematogenous spread. Infection often occurs in long bones in which the slow vascular flow within the looped vessels of the metaphysis combined with microtrauma is believed to encourage seeding of infection during a bacteraemia (Figure 41.34a). Inflammation follows and, if purulent material develops, the pressure effects of the subsequent abscess will lead to progressive bony destruction. Pus can pass through cortical bone and will then elevate the strong periosteum which may render the cortical bone avascular. As in cases of trauma or tumour, the periosteal elevation is a potent stimulus for new bone formation. In cases of untreated or chronic infection this new bone or involucrum may surround the dead bone, the sequestrum, leading to a 'bone-within-a-bone' appearance (Figure 41.34b).

The presentation and investigation of osteomyelitis is similar to that for joint sepsis. The differentiation between the two may be difficult and a sympathetic joint effusion may occur with

Figure 41.33 Septic arthritis of the right hip. (a) Anteroposterior pelvic x-ray with subtle signs of right hip subluxation. (b) Anteroposterior pelvic x-ray six months later showing destruction of the femoral head secondary to late treatment of a septic joint.

metaphyseal osteomyelitis. Thus, if there are no organisms seen on microscopy of a joint aspirate the possibility of a coexisting osteomyelitis must be considered. The metaphysis of a long bone may be intracapsular and infection may spread easily into the joint once the periosteum is breached. In the neonate, proximal femoral osteomyelitis and septic arthritis are essentially the same condition (Figure 41.34c).

General principles for the management of infection should be followed. Pus needs to be drained but otherwise the treatment is medical. Debate continues over the treatment and indeed whether antibiotics should be parenteral or oral (Summary box 41.26).

Summary box 41.26

Occurrence and treatment principles for bone and soft tissue infection

- Occurs by haematogenous spread, enhanced by microtrauma
- If untreated, new involucrum envelops dead sequestrum
- A joint effusion may be sympathetic or caused by direct spread from the adjacent metaphysis
- Treatment is drainage of pus, when present, appropriate and often prolonged antibiotic therapy, pain relief and splintage
- Rest/splintage of affected limb
- Analgesia
- Surgical drainage of pus
- Appropriate antibiotics via a suitable route and for the correct time
- Treatment of the underlying condition, e.g. nutritional deficiency, sickle cell disease

Complications of bone and joint sepsis

Treated appropriately, most cases of bone and joint sepsis resolve with no sequelae. However, significant complications can occur, particularly in terms of chronic infection and in cases in which there has been damage to the joint and/or the physis and the epiphyseal growth centres. In the neonate, vascular channels pass through the physis, connecting the metaphysis with the epiphysis, and a poorer outcome may ensue (see Figure 41.33b). Orthopaedic follow up should be continued until normal growth patterns are documented.

Meningococcal sepsis

The often debilitating, late orthopaedic sequelae of meningococcal septicaemia are secondary to endotoxin-induced microvascular injury and ischaemic physal damage.

Tuberculosis

Tuberculosis is still common. The clinical presentation is often insidious, with malaise and weight loss combined with a boggy joint swelling, muscle wasting and joint contractures. Spinal deformity and neurological symptoms are particular problems.

Chronic relapsing/recurrent multifocal osteomyelitis

X-ray features suggest subacute or chronic osteomyelitis but laboratory and histopathological findings are usually non-specific and cultures negative. This is probably an inflammatory rather than an infective condition.

Figure 41.34 Diagrams illustrating the pathology underlying the development of osteomyelitis. The longer the infection goes untreated, the greater the destruction, with the possibility of sequestrum formation and secondary joint infection.

Discitis

Children who refuse to weight-bear and complain of back pain may have discitis. The aetiology of this condition may be infective or inflammatory but if vertebral bodies are involved, infection is assumed.

Brodie's abscess

Chronic infections may present with x-ray features of a sclerotic walled cyst.

CLINICAL DILEMMAS

The limping child

Children may limp because of pain, weakness, deformity or to gain attention: the causes vary from sepsis to a spinal tumour and from a leg length discrepancy to a shoe that rubs. Serious causes must be excluded and the 'surgical sieve' helps identify the most likely diagnoses (Summary box 41.27).

Summary box 41.27

A guide to the clinical assessment of the limping child

- Symptom onset: sudden or gradual?
- Symptom duration
- Concurrent events: recent viral infection, trauma, new shoes, new sport?
- General health: is the child well?

The examination must include all joints and soft tissues and, in addition, a brief neurological examination, measurement of leg length and an assessment of pain at rest or on weight bearing.

Many conditions, such as sepsis and juvenile arthritis, can present at any age but certain hip conditions are more likely in particular age groups (Table 41.17).

Plain x-rays should usually include both anteroposterior and 'frog' lateral views of the pelvis. Always bear in mind the possibility of a tumour; further imaging such as MRI may be required.

Figure 41.35 Anteroposterior x-ray of a knee showing metaphyseal corner fractures that are often considered to be pathognomonic of non-accidental injury. Non-accidental injury must also be considered in any fracture that presents late or without an adequate explanation.

Summary box 41.28

Factors that raise concern in the clinical assessment of suspected non-accidental injury

History

- Delay in seeking medical advice
- Variable story
- Mechanism inconsistent with injury pattern

Examination

- Unexpected bruising to the buttocks/back of legs
- 'Finger-mark' bruises
- Bruising of various ages
- Burns, deep scratches, etc.

Summary box 41.29

Fracture patterns with a high specificity for NAI

- Corner or bucket-handle metaphyseal fractures
- Multiple fractures at different stages of healing/old fractures
- Scapular fractures
- Posterior rib fractures
- Any fracture in a child below walking age

Table 41.17 Age at presentation of certain hip conditions.

Age (years)	Diagnosis
1–3	Late presenting developmental dysplasia of the hip; sepsis
3–10	Transient synovitis; Perthes' disease
11–15	Slipped upper femoral epiphysis

Non-accidental injury

No child is exempt but some children are at particular risk, including those under three years and those with disabilities. A careful clinical assessment is required (Figure 41.35) (Summary box 41.28). Characteristic patterns should warn the clinician to consider the possibility (Summary box 41.29).

Child abuse occurs in different forms: emotional, physical, sexual and neglect. When suspected it should be discussed with the relevant child protection team. All injuries should be documented carefully. It may be prudent to admit the child until further checks have been made.

PART

6

Skin and subcutaneous tissue

42 Skin and subcutaneous tissue

577

LEARNING OBJECTIVES

To understand:

- the structure and functional properties of skin
- the classification of vascular skin lesions

To be aware of:

- the cutaneous manifestations of generalised disease as related to surgery

To know:

- the classification of benign skin tumours
- the management of malignant skin tumours

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF SKIN

Skin can be divided into an outer layer: the epidermis and an inner layer: the dermis. Deep to the dermis is the hypodermis which is composed of subcutaneous fat and remnants of the panniculus carnosus.

Epidermis

The epidermis is composed of keratinised stratified squamous epithelium and can be further subdivided into five layers: the stratum basale (deepest), the stratum spinosum, the stratum granulosum, the stratum lucidum and the stratum corneum (superficial) (Figure 42.1). It accounts for 5 per cent of the total skin (Summary box 42.1).

Summary box 42.1

Epidermis

- Stratum basale
- Stratum spinosum
- Stratum granulosum
- Stratum lucidum
- Stratum corneum

Dermis

- Papillary layer
- Reticular layer

Figure 42.1 Three-dimensional diagram of the structural layers of the skin and its adnexal structures. (Reproduced from Simonsen T, Aarbakke J, Kay I *et al.* *Illustrated pharmacology for nurses*. London: Hodder Arnold, 2006 with kind permission of the illustrator Roy Lysaa.)

The majority of epidermal cells are keratinocytes arranged in layers. The basal epidermis (stratum basale) also contains melanocytes. Keratinocytes are classified according to their depth in the epidermis and their degree of differentiation. Keratinocytes grow and are replaced via mitoses in the cells of the stratum granulosum as they progress from deep to superficial, losing their nuclei and organelles as they progress upwards before forming the stratum corneum. The other keratinocyte layers in the skin (the strata lucidum; granulosum and spinosum) are variably present according to body site – for instance all three are present in the glabrous skin of the palms and soles of the feet.

Melanocytes are dendritic cells of neural crest origin usually located in the basal epidermis. Each melanocyte synthesises the brown-black pigment melanin, which is transferred via membrane processes to the keratinocytes in the strata granulosum and spinosum. Melanin provides protection against ultraviolet radiation. Ethnic differences in skin colour are determined by variations in the amount, combination and distribution of melanin within the keratinocytes, rather than differences in the number of melanocytes.

Dermis

The dermis comprises 95 per cent of the skin and is structurally divided into two layers. The superficial papillary layer is composed of delicate collagen and elastin fibres in ground substance, into which a capillary and lymphatic network ramifies. The deeper reticular layer is composed of coarse branching collagen, layered parallel to the skin surface.

The epidermis and dermis meet at the dermoepidermal junction in a three-dimensional wave-like arrangement in which epidermal rete pegs project down and interdigitate with upward-pointing, dermal papillary ridges containing vascular and lymphatic plexi.

The skin also contains specialised cells such as Langerhan's cells, whose role is to engulf antigens and present them to T cells. Merkel cells, Meissner's and Pacinian corpuscles have a role in mechanosensation.

Skin adnexia

Adnexial structures such as hair follicles, sebaceous and sweat glands span both the epidermal and dermal layers and contain some keratinocytes in their ducts. In injuries where epidermis is lost, re-epithelialisation occurs from these structures as well as from the wound margins.

Hair follicles

The human body is covered by fine downy hair (vellus) for three months *in utero*. This is eventually shed before birth, apart from the eyebrows and lashes. Hair which grows out from a hair bulb at the base of a follicle (tubular invaginations of the epidermis) is a shaft of dead keratinised tissue. Strips of smooth muscle (erector pili) are inserted into the wall of the hair follicle and lead to hair elevation in times of stress and cold.

Sebaceous glands

Most are hair follicle appendages situated between each hair follicle and its erector pili muscle. When the erector pili muscle contracts to elevate the hair, it compresses the gland and sebum

is released (holocrine secretion). The function of the sebum is to act as a skin lubricant and physical protection barrier.

Sweat glands

Eccrine and apocrine are simple sweat glands that open into pores in hair follicles. Eccrine glands are distributed throughout the entire body surface except on the lips. These glands secrete sweat in response to emotion or as part of thermoregulation. Apocrine glands are found in the axillary and groin areas and become active at puberty. Their secretion, which is characteristically malodorous, varies in response to emotion, hormone secretion and bacterial degradation.

Skin thickness

Skin thickness varies with age and body area. It is thinner in children than in adults in any given region. The dermis is between 15 and 40 times thicker than the epidermis, but starts to thin during the fourth decade as part of the ageing process. The epidermis is thickest on the palms, soles, back and buttocks and thinnest on eyelids (0.5–1 mm on sole of the foot, 0.05–0.09 mm on the eyelid).

Blood supply of the skin

In the last 25 years, the 'angiosome model' has furthered our understanding of the anatomical blood supply of skin and therefore the ability to reconstruct soft tissue defects using vascularised flaps of various tissue compositions. With respect to its blood supply, the body can be envisaged as three-dimensional segments of tissue called angiosomes, each with an arterial supply and a venous drainage. Blood equilibrates and flows between neighbouring angiosomes via 'choke' vessels, which tend to be situated within muscles. Cutaneous arteries, direct branches of segmental arteries (concentrated at the dorsoventral axes and intermuscular septae), perforate the underlying muscles or run directly within fascial layers to the skin from the deep tissues (Figure 42.2).

The blood supply to the skin anastomoses in subfascial, fascial, subdermal, dermal and subepidermal plexi. The epidermis contains no blood vessels so cells there derive nourishment by diffusion.

The venous drainage of the skin is via both valved and un-valved veins. The unvalved veins allow an oscillating flow between cutaneous territories within the subdermal plexus – equilibrating flow and pressure. The valved cutaneous veins drain via plexi to the deep veins.

Anomalies of skin metabolism

Blood flow to the skin can vary between 5 and 100 mL 100 g/min in the temperature range 20–40°C. The skin thus has a potential blood supply that is 20–100 times greater than its metabolic and thermoregulatory requirements. Despite this, the blood supply is inadequate to support wound healing alone – primary closure or granulation tissue is therefore required for healing to occur.

A teleological explanation for this apparent excess blood supply is in the restitution of mechanical integrity after the myriad injuries such as scratching, stretching, compressing, heating and cooling to which our skin is constantly subjected.

Skin functions optimally at temperatures below body core temperature and can tolerate long periods of ischaemia (allowing it both to be grafted and to be expanded and used in reconstructive surgery, see Chapter 31).

George Meissner, 1829–1905, successively Professor of Anatomy and Physiology, Basle, Switzerland, Professor of Zoology and Physiology, Freiberg, Germany and Professor of Physiology, Göttingen, Germany.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.

Friedrich Sigmund Merkel, 1845–1919, Professor of Anatomy successively at Rostock, Königsberg (now Kaliningrad in Russia) and Göttingen, Germany.

Filippo Pacini, 1812–1883, Professor of Anatomy and Physiology, Florence, Italy.

Figure 42.2 Schematic showing two neighbouring angiosomes. Note the choke vessels within the muscle spanning the two cutaneous territories of angiosome A and B – two common examples of myocutaneous flaps which utilise this physiology include the rectus abdominus and the latissimus dorsi flaps.

FUNCTION OF THE SKIN

Human skin and subcutaneous tissue have several important functions (Summary box 42.2).

Summary box 42.2

Function of the skin

- Barrier to the environment: trauma, radiation, pathogens
- Temperature and water homeostasis
- Excretion (e.g. urea, sodium chloride, potassium, water)
- Endocrine and metabolic functions
- Sensory organ for pain, pressure, movement

Skin grafts

Grafts of the skin can be used to reconstruct wounds having been harvested as split (leaving some epidermal components) or full thickness. The process by which a skin graft adheres to and heals a wound is a unique and unnatural process, in which normal wound healing at the recipient site is altered by the presence of the graft. The survival of a skin graft is largely dependent on how fast the graft derives new blood supply from the wound on which it is placed. Until the graft establishes a new blood supply, nutrition is derived by diffusion through the fibrin layer formed between it and the wound bed. After 48–72 hours, a fine capillary network grows into the graft and anastomoses with the native vasculature of the graft. Factors that inhibit this process (haematoma, seroma or bacterial exudates) will decrease the likelihood that the graft will successfully ‘take’ (see Chapter 31).

Ulcers

An ulcer is a discontinuity of an epithelial surface. It is characterised by progressive destruction of the surface epithelium and a granulating base. Ulcers can be classified as non-specific, specific and malignant (Table 42.1 and Figure 42.3).

Sinus

A sinus is a blind-ending tract that connects a cavity lined with granulation tissue (often an abscess cavity) with an epithelial surface. Sinuses may be congenital or acquired (Table 42.2). Congenital sinuses arise from the remnants of embryonic ducts that persist instead of being obliterated and involuted during embryonic development. Acquired sinuses occur as a result of the presence of a retained foreign body (for example suture material), specific chronic infection (for example tuberculosis (TB) or actinomycosis), malignancy or inadequate drainage of the cavity (Figure 42.4).

Treatment of the sinus is directed at removing the underlying cause. Biopsies should always be taken from the wall of the sinus to exclude malignancy or specific infection.

For specific management of the disease conditions please refer to the appropriate chapter.

Fistula

A fistula is an abnormal communication between two epithelium lined surfaces. This communication or tract may be lined by granulation tissue but may become epithelialised in chronic cases. Fistulas may be congenital or acquired.

Examples of congenital fistula include tracheo-oesophageal and branchial fistulas. Acquired fistulas include fistula in ano, enterocutaneous fistula following Crohn’s disease or postoperative anastomotic complications, arteriovenous fistula which may

Table 42.1 Classification of common types of ulcer.

Ulcer	Type
Peptic	Non-specific
Pressure sores (decubitus ulcers) and ischaemic ulcers	Non-specific
Gravitational ulcers – venous insufficiency	Non-specific
Secondary infective – wound infection and abscess drainage	Non-specific
Traumatic ulcers	Non-specific
Neuropathic ulcers – diabetes, tabes dorsalis, leprosy	Non-specific
Iatrogenic – intravenous fluid extravasation	Non-specific
Dermatitis artefacta – self-mutilation	Non-specific
Aphthous	Non-specific
Primary infective – herpes simplex, tuberculosis, fungal, syphilis	Specific
Gastrointestinal tract and skin	Malignant

Table 42.2 Sinuses.

Congenital	Acquired
Preauricular	Post surgical (abdominal or perineal)
Umbilical	Pilonidal
Urachal	Suture
Coccygeal	TB
Sacral	Actinomycosis
	Osteomyelitis
	Crohn's disease

be traumatic or iatrogenic (for haemodialysis).

Again, management of the fistula is directed to treating the underlying aetiology (see appropriate chapter).

PATHOPHYSIOLOGY OF THE SKIN AND SUBCUTANEOUS TISSUES

Radiation damage

Ultraviolet radiation (UVR) and ionising radiation (IR) damage cellular DNA via the tumour suppressor gene *p53*, inhibiting cellular repair and apoptotic mechanisms. There is also evidence that efferent immune responses are impaired after skin exposure to ultraviolet radiation facilitating neoplasia.

Ultraviolet radiation

UVR is divisible into A, B and C according to wavelength. UVR is the principal cause of skin cancer in all skin types. Its effects are attenuated by melanin and there is an inverse relationship between melanin content and skin susceptibility to UV-induced neoplasia. Some protection is afforded by the stra-

Figure 42.3 Some characteristic shapes of the edges of ulcers. (a) Non-specific ulcer: note the shelving edge. (b) Tuberculous ulcer: note the undermined edge. (c) Basal cell carcinoma (rodent ulcer): note the rolled edge, which may exhibit small blood vessels. (d) Epithelioma: note the heaped-up, everted edge and irregular thickened base. (e) Syphilis: note the punched-out edge and thin base, which may be covered with a 'wash-leather' slough.

Figure 42.4 A sinus (a) and a fistula (b); both usually arise from a preceding abscess. (a) This is a blind track, in this case a pilonidal abscess. (b) This is a track connecting two epithelium-lined surfaces, in this case a colocutaneous fistula from colon to skin.

tum corneum, which reflects and refracts UVR and by clothing, protective creams, cloud cover and buildings.

Ionising radiation

The effects of IR are dose and time dependent. The skin with its rapid cellular turnover exhibits signs soon after exposure. High frequency rays cause electron coupling at the molecular level damaging proteins, polysaccharides and lipids.

Infrared radiation

Infrared radiation generates heat with cumulative exposure posing the risk of thermal burns (see Chapter 30).

Congenital/genetic disorders

Neurofibromatosis

There are two distinct neurofibromatosis syndromes where Schwann cells form tumours (Figure 42.5). Each is caused by different genes on different chromosomes. Seventy per cent are

Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy successively at Louvain (1839–1848) and Liege, Belgium (1849–1880). Original researches before the age of 27 laid the foundation of physiology of nerve and muscle. The first to deal with problems related to living matter on a purely physical and chemical basis, and to recognise the cell as the unit of living matter. Discoverer of pepsin, and role of living organisms in fermentation.

Figure 42.5 Neurofibromatosis (courtesy of St John's Institute for Dermatology, London, UK).

autosomal dominant and 30 per cent arise from sporadic mutations. Neurofibromatosis (NF) 1 or von Recklinghausen's disease is the more common variant, affecting approximately 1:4000 births. It arises from a gene mutation on chromosome 17. Skin manifestations can appear in early life, with the development of more than five smooth-surfaced café-au-lait spots, subcutaneous neurofibromata, armpit or groin freckling and Lisch nodules.

Naevoid basal cell carcinoma (Gorlin's) syndrome

This is an autosomal dominant inherited condition caused by an abnormality in the tumour suppressor gene on chromosome 9q22-31 that codes for the 'patched' protein. Ninety per cent of patients develop multiple basal cell carcinomas. Patients may also exhibit specific phenotypical characteristics including overdeveloped supraorbital ridges, broad nasal roots, hypertelorism, bifid ribs, scoliosis, brachymetacarpalism, palmar pits and molar odontogenic cysts.

Xeroderma pigmentosum

Described by Kaposi in 1874, this syndrome is caused by an abnormality on the 'patched' gene of chromosome 9q resulting in aberrant nucleotide repair during cellular DNA maintenance. It has an autosomal recessive inheritance conferring >2000-fold increase in skin cancer risk. Sufferers have an intolerance to UVR manifested as erythema, pigmentation and photophobia. This leads to premature skin ageing and the development of multiple neoplasms, with most affected individuals dying in early adulthood from metastatic disease (60 per cent mortality by 20 years of age).

Gardner's syndrome

An autosomal dominant disease variant of familial adenomatous polyposis (FAP) is caused by an abnormal gene on chromosome 5. Gardner's syndrome can cause the development of cutaneous pathology such as multiple epidermoid cysts and lipomata.

Ferguson-Smith syndrome

This is a rare, autosomal-dominantly inherited abnormality on chromosome 9q (Figure 42.6). This results in a syndrome that

Figure 42.6 Mid-face of a patient with Ferguson-Smith syndrome. Note the two tumours at different stages of development: on the nose and the right cheek (courtesy of St John's Institute for Dermatology, London, UK).

can be traced to a single familial line from western Scotland with affected individuals developing multiple self-healing squamous cell carcinomas.

Cutaneous manifestations of generalised disease

Many diseases have cutaneous manifestations that may present in surgical practice. These include necrobiosis lipoidica, granuloma annulare in diabetes mellitus and pyoderma gangrenosum in inflammatory bowel disease.

Hyperhidrosis

This condition involves excessive eccrine sweating of the palms, soles of the feet, axillae and groins. This can cause functional and social problems, but can be controlled depending on severity, with anti-perspirants or periodic local injections with botulinum toxin A. More resistant cases are treated by laparoscopic cervical sympathectomy.

Lipodystrophy

Lipodystrophy (lipoatrophy) is a localised or generalised loss of fatty tissue which can have primary or secondary causes. It is most commonly seen as a complication of long-term administration of insulin, following treatment of HIV with protease inhibitors or in transplant recipients.

It can be treated in selected cases by autologous fat grafting, injections of poly-L-lactic acid and free tissue transfer.

Inflammatory conditions

Hidradenitis suppurativa

This is a chronic inflammatory disease culminating in suppurative skin abscesses, sinus tracts and scarring (Figure 42.7). It most commonly occurs in the apocrine gland containing skin, namely in the axillary and groin areas. Less common sites include the scalp, breast, chest and perineum.

Hidradenitis suppurativa appears to have a genetic predisposition with variable penetrance, and is strongly associated with obesity and smoking. Women are four times more likely affected than men.

The pathophysiology involves follicular occlusion followed by folliculitis and secondary infection with skin flora (usually *Staphylococcus aureus* and *Propionibacterium acnes*). Clinically, patients develop tender, subcutaneous nodules which may not

Friedrich von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.

Karl Lisch, 1907–1999, ophthalmologist, Wörgl, Austria.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria.

John Francis Ferguson-Smith, 1888–1978, dermatologist, The Victoria Infirmary, Glasgow, UK.

Eldon J Gardner, 1909–1989, Professor of Zoology, Utah State University, Salt Lake City, UT, USA.

Figure 42.7 Hidradenitis suppurativa affecting the axilla (courtesy of St John's Institute for Dermatology, London, UK).

point and discharge, but which usually progress to cause chronic inflammation and scarring.

Management

Patients should be advised to stop smoking and lose weight where appropriate. Symptoms can be reduced by the use of antiseptic soaps, tea tree oil, non-compressive and aerated underwear.

Medical treatments include topical and oral antibiotics and anti-androgen drugs.

In selected cases, patients may require radical excision of the affected skin and subcutaneous tissue with reconstruction. Healing by secondary intention more frequently leads to contracture and functional impairment than when plastic surgical techniques, such as skin grafting or flap transposition are employed.

Pyoderma gangrenosum

Pyoderma gangrenosum is characterised by cutaneous ulceration with purple undermined edges (Figure 42.8). It is secondary to heightened immunological reactivity, usually from another disease process such as inflammatory bowel disease; rheumatoid arthritis, non-Hodgkin's lymphoma or Wegener's granulomatosis.

Cultures from ulcers often grow Gram-negative streptococci. These skin lesions generally respond to steroids. Surgery is rarely indicated and may exacerbate the condition.

Infections

Skin and soft tissue infections can be localised or spreading, necrotising or non-necrotising. Localised or spreading, non-necrotising infections usually respond to broad-spectrum antibiotics. Localised necrotising infections will need surgical debridement as well as antibiotic therapy. Spreading, necrotising soft tissue infection constitutes a life-threatening surgical

Figure 42.8 Pyoderma gangrenosum affecting the legs (a) and the breasts (b) (courtesy of St John's Institute for Dermatology, London, UK).

emergency, requiring immediate resuscitation, intravenous antibiotic therapy and urgent surgical intervention with radical debridement.

Impetigo

Impetigo is a superficial skin infection with staphylococci, streptococci or both (Figure 42.9). It is highly infectious and usually affects children. Impetigo is characterised by blisters that rupture and coalesce to become covered with a honey-coloured crust. Treatment is directed at washing the affected areas and applying topical anti-staphylococcal treatments, and broad-spectrum oral antibiotics if streptococcal infection is implicated.

Erysipelas

Erysipelas is a sharply demarcated streptococcal infection of the superficial lymphatic vessels, usually associated with broken skin on the face (Figure 42.10). The area affected is erythematous and oedematous. The patient may be febrile and have a leukocytosis. Prompt administration of broad-spectrum antibiotics after swabbing the area for culture and sensitivity is usually all that is necessary.

Cellulitis/lymphangitis

This is a bacterial infection of the skin and subcutaneous tissue that is more generalised than erysipelas (Figure 42.11). It is usually associated with broken skin or pre-existing ulceration. Cellulitis is characterised by an expanding area of erythematous,

Figure 42.9 Impetigo. Note the honey-coloured crust (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.10 Erysipelas (courtesy of St John's Institute for Dermatology, London, UK).

oedematous tissue that is painful and associated with a fever, malaise and leukocytosis. Erythema tracking along lymphatics may be visible (lymphangitis). The most common causative organism is streptococcus. Blood and skin cultures for sensitivity should be taken before prompt administration of broad-spectrum intravenous antibiotics and elevation of the affected extremity.

Necrotising fasciitis

Necrotising fasciitis was first described by Paré in the sixteenth century. Meleney's synergistic gangrene and Fournier's gangrene are all variants of a similar disease process (Summary box 42.3).

Necrotising fasciitis results from a polymicrobial, synergistic infection, most commonly a streptococcal species (group A β haemolytic) in combination with *Staphylococcus*, *Escherichia coli*, *Pseudomonas*, *Proteus*, *Bacteroides* or *Clostridia*. Eighty per cent have a history of previous trauma/infection and over 60 per cent

Figure 42.11 Cellulitis affecting the left leg (courtesy of St John's Institute for Dermatology, London, UK).

Summary box 42.3

Necrotising fasciitis

- Surgical emergency
- Polymicrobial synergistic infection
- 80 per cent history of previous trauma or infection
- Rapid progression to septic shock
- Urgent resuscitation, antibiotics and surgical debridement
- Mortality 30–50 per cent

commence in the lower extremities. Predisposing conditions include:

- diabetes;
- smoking;
- penetrating trauma;
- pressure sores;
- immunocompromised states;
- intravenous drug abuse;
- perineal infection (perianal abscess, Bartholin's cysts);
- skin damage/infection (abrasions, bites, boils).

Classical clinical signs include: oedema stretching beyond visible skin erythema; a woody hard texture to the subcutaneous tissues; an inability to distinguish fascial planes and muscle groups on palpation; disproportionate pain in relation to the affected area with associated skin vesicles and soft tissue crepitus (Figure 42.12). Lymphangitis tends to be absent. Early on, patients may be febrile and tachycardic, with a very rapid progression to septic shock. Radiographs should not delay treatment but if taken, they may demonstrate air in the tissues.

Ambrose Paré, 1510–1590, a French military surgeon who also worked at the Hôtel Dieu, Paris, France. He was regarded as the great official royal surgeon for the kings. He devised a dressing of egg white, oil of roses and turpentine which he applied to the wounds of soldiers successfully. He also developed the ligature as a means to stop bleeding.

Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Columbia University, New York, NY, USA.

Jean Alfred Fournier, 1832–1915, syphilologist, founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

Management should commence with urgent fluid resuscitation, monitoring of haemodynamic status and administration of high-dose broad-spectrum intravenous antibiotics. This is a surgical emergency and the diseased area should be debrided as soon as possible until viable, healthy, bleeding tissue is reached. Early re-look and further debridement is advisable together with the use of vacuum-assisted dressings. Early skin grafting in selected cases may minimise protein and fluid losses. Mortality of between 30 and 50 per cent can be expected even with prompt operative intervention.

Purpura fulminans

This is a rare condition in which intravascular thrombosis produces a rapid skin necrosis with haemorrhagic skin infarction. This progresses rapidly to septic shock and disseminated intravascular coagulation. It is usually seen in children, but can occur in adults. It may be sub-divided into three types based on aetiological mechanism.

Acute infectious purpura fulminans

This is the most common form of purpura fulminans and is caused by either an acute bacterial or viral infection (Figure 42.13). *Neisseria meningitidis* and varicella are the most common causal organisms. Acute infectious purpura fulminans causes an acquired protein C deficiency as endotoxins produce an imbalance in the procoagulant and anticoagulant endothelial activity.

Acute infectious purpura fulminans is most common in children under seven years, following an upper respiratory tract infection or in asplenia. Clinically, an initial petechial rash is observed. This develops into confluent ecchymoses and haemorrhagic bullae, which in turn necrose to form well-demarcated lesions that form hard eschars. Extensive tissue loss is common which often culminates in limb amputation. Acute infectious purpura fulminans is associated with a mortality rate of 40–50 per cent, usually a result of multiorgan failure.

Neonatal purpura fulminans

This is an inherited deficiency of protein C and protein S and primarily affects children causing extensive venous thrombosis of the skin and viscera in the first days of life.

Idiopathic purpura fulminans

Usually follows a viral illness after a latent period before the development of the clinical picture of purpura fulminans.

Skin and soft tissue cysts

Milia

These are tiny hard keratin retention cysts seen both in babies and the elderly after chronic sun exposure damage (Figure 42.14).

Epidermal cysts

These are cysts lined with true stratified squamous epithelium derived from the infundibulum of the hair follicle or traumatic inclusion. They are commonly known as sebaceous cysts and are often found on hairy areas of the body, such as the scalp, trunk and face. They are fixed to the skin and usually have a central punctum that is often indentable (Figure 42.15).

Treatment depends on the clinical state of the cyst. When they are inflamed or infected they should be incised and drained

initially, and subsequently removed approximately 6 weeks later once the inflammation and induration has subsided. It is important to excise the cyst in its entirety as failure to do so usually results in recurrence.

Meibomian cysts are epidermal cysts found on the free edge of the eyelid. A chronic Meibomian cyst is called a chalazion. Tricholemmal (pilar/pilosebaceous) cysts can be confused with epidermal cysts, except they are derived from the epidermis of the external root sheath of the hair follicle. Ninety per cent are found in the scalp and 70 per cent are multiple.

Figure 42.14 Milia (courtesy of St John's Institute for Dermatology, London, UK).

SKIN TUMOURS

Benign lesions

Basal cell papilloma (seborrhoeic keratosis, senile keratosis, verruca senilis)

These are soft warty lesions, which are often pigmented and hyperkeratotic. They are formed from the basal layer of epidermal cells and contain melanocytes. They are one of the most common benign skin tumours in the elderly (Figure 42.16).

Papillary wart (verruca vulgaris)

This is a benign skin tumour arising from infection with the human papilloma virus, which is also responsible for plantar warts and condylomata acuminata.

Freckle (ephelis)

A freckle is an area of skin that contains a normal number of melanocytes, producing an abnormally large number of melanin granules.

Lentigo

Lentigenes are small, sharply circumscribed pigmented macules which are a marker for sun damage and some systemic syndromes. Solar lentigenes are more common in fairer skins. An example of a systemic syndrome associated with lentigenes is Peutz-Jeghers syndrome.

Moles/naevi

Melanocytes migrate from the neural crest to the basal epidermis during embryogenesis. When these melanocytes layer in the epidermis they form a simple mole. Melanocytes that aggregate in the dermis or at the dermoepidermal junction are called naevus cells.

Junctional naevus

A junctional naevus is a deeply pigmented macule or papule that occurs commonly in childhood or adolescence (Figure 42.17). It represents a dermoepidermal proliferation of naevus cells, which

Figure 42.15 Multiple scrotal epidermal cysts (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.16 Basal cell papilloma (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.17 Junctional naevus (courtesy of St John's Institute for Dermatology, London, UK).

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John's Hospital, The Hague, The Netherlands.

Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

usually progresses to form a compound or intradermal naevus with advancing age. It may be found on any part of the body but has no malignant potential. Benign mucosal lesions tend to be junctional naevi.

Compound naevus

This is a maculopapular, pigmented lesion that becomes most prominent during adolescence (Figure 42.18). It represents a junctional proliferation of naevus cells with nests and columns in the dermis.

Intradermal naevus

Intradermal naevi are faintly pigmented papules in adults showing no junctional proliferation but a cluster of dermal melanocytes (Figure 42.19).

Spitz naevus

These are reddish brown (occasionally deeply pigmented) nodules previously termed 'juvenile melanoma' (Figure 42.20). They most commonly occur on the face and legs, growing rapidly initially then remaining static. The differential diagnosis is melanoma and excision biopsy is warranted if there is doubt as to the diagnosis.

Spindle cell naevus

Spindle cell naevi are dense black lesions which contain spindle cells and atypical melanocytes at the dermoepidermal junction. They are commonly seen on the thighs and affect women more frequently. They may have malignant potential.

Halo naevus

The halo of depigmentation around any benign naevus represents an antibody response to melanocytes (Figure 42.21). The importance of this depigmentation is that it may also be a feature of a malignant melanoma. A halo naevus is associated with vitiligo.

Café-au-lait spots

These are coffee-coloured macules of variable size (from a few millimetres to 10 cm) (Figure 42.22). Multiple lesions are associated with neurofibromatosis type 1 and McCune–Albright syndrome. They are more common in dark-skinned races.

Naevus spilus

This is also known as speckled lentiginous naevus (Figure 42.23). It is similar in appearance to a café-au-lait spot but with hyperpigmented speckles throughout. It is a benign lesion that is associated with various cutaneous diseases. The mainstay of management is observation and serial photography as malignant transformation is rare.

Mongolian spot

A Mongolian spot is a congenital blue-grey macule found over the sacral skin area (Figure 42.24). Pigmentation initially deepens and then regresses completely by age seven years.

Blue naevus

This is a benign skin lesion that is four times more common in children, typically affecting the extremities and face (Figure 42.25).

Figure 42.18 Compound naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.19 Intradermal naevus (courtesy of St John's Institute for Dermatology, London, UK).

Naevi of Ota and Ito

The naevus of Ota is a dermal melanocytic hamartoma with a characteristically blue or grey macule in the trigeminal V₁ and V₂ dermatomes (Figures 42.26 and 42.27). It is four times more common in women and most frequently seen in Oriental and African races.

The Naevus of Ito is characterised by dermal melanocytosis in the shoulder region and can occur simultaneously in a patient with naevus of Ota.

Hair follicles

Trichoepithelioma

These are small skin-coloured nodules most often found in the nasolabial fold. It is clinically and histologically similar to a basal cell carcinoma.

Sophie Spitz, 1910–1956, American pathologist. Dermatopathologist at Sloan-Kettering Cancer Center, published the first case series of 'juvenile melanoma' in 1948. Died at the age of 46 from carcinoma of the colon.

Figure 42.20 Spitz naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.21 Halo naevus (courtesy of St John's Institute for Dermatology, London, UK).

Pilomatrixoma (calcifying epithelioma of Malherbe)

These are benign tumours of hair matrix cells characterised by basaloid and eosinophilic ghost cells. They commonly calcify and 40 per cent are found in the under-10 age group.

Tricholemmoma (naevus sebaceous of Jadassohn)

Tricholemmoma is a congenital hamartoma with the appearance of a linear verrucous naevus. These are believed to form basal cell carcinomata (BCC) in up to 10 per cent of cases (Figure 42.28).

Adenoma sebaceum (tuberous sclerosis, Bourneville disease)

These are typically red facial papules (angiofibromas) found usually on the nasolabial folds, cheek and chin (Figure 42.29). They form part of the disease process in tuberous sclerosis. These skin lesions usually appear in children less than ten years of age and increase in size and number until adolescence. Cosmetic removal by argon or pulse dye lasers or scalpel is indicated.

Figure 42.22 Café-au-lait spots. Note the two topographical variants: in (a) the spot has a smooth 'coast of California' border, whereas the upper spot in (b) has an irregular 'coast of Maine' border. Multiple smooth-bordered lesions are commonly associated with syndromes (courtesy of St John's Institute for Dermatology, London, UK).

Rhinophyma

Rhinophyma is the end-stage sequela of acne rosacea (Figure 42.30). It is a hypertrophy and hyperplasia of the sebaceous glands and tends to affect elderly men (M:F 12:1). Up to 3 per

Figure 42.23 Naevus spilus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.25 Blue naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.24 Mongolian spot (courtesy of St John's Institute for Dermatology, London, UK).

cent of cases may have an occult BCC. Treatment by dermabrasion or laser resurfacing produces good results.

Sweat glands

Cystadenoma (hydrocystadenomas, hidradenomas)

These are 1–3-cm translucent blue cystic nodules.

Eccrine poroma (papillary syringoma)

These are single raised or pedicled lesions found most often on the palm or sole.

Cylindroma (turban tumour)

A variant of eccrine spiradenoma which can be multiple on the scalp and can coalesce to form a 'turban tumour'.

Figure 42.26 Naevus of Ota (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.27 Naevus of Ito (courtesy of St John's Institute for Dermatology, London, UK).

Premalignant lesions

Actinic/solar keratosis

These are areas of dyskeratosis and cellular atypia, with sub-epidermal inflammation, but a normal dermoepidermal junction

Figure 42.28 Naevus sebaceus of Jadassohn (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.29 Adenoma sebaceum (courtesy of St John's Institute for Dermatology, London, UK).

(Figure 42.31). However, up to 20 per cent go on to form squamous cell carcinomas.

Cutaneous horn

A cutaneous keratin accumulation which by definition has a height greater than its base diameter. Ten per cent will have an underlying squamous cell carcinoma (SCC) (Figure 42.32).

Keratoacanthoma

Classically, this is a symmetrical, cutaneous growth with a central crater filled with a keratin plug (Figure 42.33). It is twice as common in men and is usually found on the face of 50–70 year olds. The aetiology of keratoacanthoma is unclear but may be caused by a papilloma virus in a hair follicle during the growth phase. It has also been associated with smoking and chemical carcinogen exposure.

Figure 42.30 Rhinophyma (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.31 Actinic keratosis (courtesy of St John's Institute for Dermatology, London, UK).

Keratoacanthoma can grow to between 1 and 3 cm in a 6-week period and then typically resolve spontaneously over the subsequent six months. Removal of the central keratin plug may speed resolution. Excision is recommended as the differential diagnosis includes anaplastic SCC and the excision scar is often better than that which remains after resolution.

Bowen's disease

Bowen's disease was first described by John T Bowen in 1912. It is a carcinoma *in situ* with between 3 and 11 per cent progressing to SCC (Figure 42.34). It is currently not thought to be a paraneoplastic condition. Chronic solar damage and inorganic

Figure 42.32 Cutaneous horn (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.33 Keratocanthoma (courtesy of St John's Institute for Dermatology, London, UK).

arsenic ingestion have been implicated as aetiological factors in the development of Bowen's disease. The human papilloma virus 16 has also been documented as a cause.

Bowen's disease often presents as a slowly enlarging, erythematous, scaly patch or plaque. It may occur anywhere on the mucocutaneous surface of the body. On the glans penis, it is called erythroplasia of Queyrat (Figure 42.35).

Topical therapy with 5-fluorouracil or imiquimod are effective treatments. Alternatives include surgical excision with a 4-mm margin or Mohs' micrographic surgery for larger or recurrent lesions.

Extramammary Paget's disease

It is a form of intraepidermal adenocarcinoma, which may occur in the genital, perianal regions or in cutaneous sites rich in apocrine glands such as the axilla (Figure 42.36). Approximately 25 per cent of the cases of extramammary Paget's disease are associated with an underlying *in situ* or invasive neoplasm.

The early skin changes are subtle and may present as an eczematous lesion or intertrigo.

Surgical excision forms the basis of treatment with up to 20 per cent demonstrating invasion on excision.

Figure 42.34 Bowen's disease – squamous cell carcinoma *in situ* (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.35 Erythroplasia of Queyrat – squamous cell carcinoma *in situ* on the glans penis; also called Paget's disease of the penis (courtesy of St John's Institute for Dermatology, London, UK).

Giant congenital pigmented naevus or giant hairy naevus

The giant congenital pigmented naevus (GCPN) causes a great deal of confusion as its definition and management is contentious. It is a hamartoma of naevo-melanocytes that has a tendency to dermatomal distribution (Figure 42.37). It has a similar histology to compound naevi, but the naevus cells are distributed variably from the epidermis throughout all layers and into the subdermal fat and muscle. There is general agreement that

Frederic E Mohs, 1910–2002, a twentieth century American Surgeon, Physician and General Surgeon, University of Wisconsin, Madison, WI, USA. Developed the Mohs Micrographic Surgical technique in 1938 for cutaneous malignant lesions.

Figure 42.36 Extramammary Paget's disease involving perineum (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.37 Giant congenital pigmented naevus (courtesy of St John's Institute for Dermatology, London, UK).

GCPNs are precursors of melanoma but the magnitude of this risk is unclear largely due to the lack of well-conducted studies and poor classification. A 3–5 per cent lifetime risk of melanoma is quoted. One in three childhood malignant melanomas arise in patients with GCPN but the risk decreases with age with 15 per cent presenting at birth, 62 per cent present by puberty and 99 per cent by 45 years of age.

A multidisciplinary management approach is advocated with initial investigations examining for neurocutaneous melanosis as there may be leptomeningeal involvement. Removal of GCPN should be considered for both aesthetic and oncological reasons.

Dysplastic (atypical) naevus

Dysplastic naevus is an irregular proliferation of atypical melanocytes at the basal layer of epidermis (Figure 42.38). It has variegated pigmentation with irregular borders, measuring more than 5 mm in size. Dysplastic naevus has a familial inheritance and carries a 5–10 per cent risk of forming a superficial spreading melanoma.

Malignant lesions

Basal cell carcinoma

Usually a slow growing, locally invasive malignant tumour of pluripotential epithelial cells arising from basal epidermis and hair follicles, hence affecting the pilosebaceous skin (Summary box 42.4).

Summary box 42.4

Basal cell carcinoma

- Slow growing
- Risk factor – ultraviolet light
- 90 per cent nodular/nodular cystic
- High and low risk basal cell carcinoma

Epidemiology

The strongest predisposing factor to BCC is ultraviolet radiation. The incidence of BCC therefore rises with proximity to the equator, although 33 per cent arise in parts of the body which are not sun exposed. It occurs in the middle aged or elderly with 90 per cent of lesions found on the face above a line from the lobe of the ear to the corner of the mouth. Other predisposing factors include exposure to arsenical compounds, coal tar, aromatic hydrocarbons, ionising radiation and genetic skin cancer syndromes. White-skinned people are almost exclusively

Figure 42.38 Dysplastic naevus (courtesy of St John's Institute for Dermatology, London, UK).

affected. Ninety-five per cent occur between the ages of 40 and 80 years and are more common in men.

Pathogenesis

BCCs have no apparent precursor lesions and their development is proportional to the initial dose of the carcinogen, but not duration of exposure. BCCs rarely metastasise, are hard to culture and resist transplantation. All of this suggests that a multistep mechanism for their development is unlikely, and that mesodermal factors acting as intrinsic promoters coupled with an initiation step is the most likely mechanism.

Macroscopic

BCC can be divided into localised (nodular, nodulocystic, cystic, pigmented and naevoid) and generalised lesions. These lesions can be superficial (multifocal or superficial spreading) or infiltrative (morphoeic, ice pick and cicatrising) (Figure 42.39). Nodular and nodulocystic variants account for 90 per cent of BCC.

Microscopic

Twenty-six histological types have been described. The characteristic finding is of ovoid cells in nests with a single 'palisading' layer. It is only the outer layer of cells that actively divide. This may explain why tumour growth rates are slower than the cell cycle speed would suggest, and why incompletely excised lesions are more aggressive. Morphoeic BCCs synthesise type 4 collagenase and so spread rapidly (Figure 42.40).

Prognosis

There are 'high risk' and 'low risk' BCCs. High risk BCCs are the ones that are large (>2 cm) and located at specific sites (near the eye, nose, ear) and have ill-defined margins. Recurrent tumours and those forming in the presence of immunosuppression are also higher risk.

Management

Treatment can be surgical or non-surgical. Margins should always be assessed and marked under loupe magnification and vary between 2 and 15 mm depending on the macroscopic variant. Where margins are ill-defined, or tissue at a premium (nose, eyes), then either Mohs' micrographic surgery or a two-stage surgical approach with subsequent reconstruction after confirmation of clear margins is advisable. The histological sample must be orientated and marked for pathological examination.

Mohs' micrographic surgery is a method used by dermatological surgeons (dermatologists who have undergone extra training in techniques of cutaneous surgery and histopathology) to excise skin cancer under microscopic control.

It has been demonstrated in suitable skin tumours to minimise recurrence rates and maximise conservation of surrounding normal tissue. This technique is therefore considered the optimal treatment for poorly demarcated, recurrent or incompletely excised BCC (including BCC around the nose, eyes and ears where clearance may be uncertain and significant morbidity is associated with incomplete excision, and where reconstruction with a flap is preferable cosmetically).

Mohs' micrographic surgery (using either frozen section and immunohistochemistry or horizontal paraffin-embedded sections) can also be used for excision of SCC, dermatofibrosarcoma protuberans and lentigo maligna.

Figure 42.39 (a) A nodulocystic basal carcinoma (BCC). Note the characteristic pearly surface with telangiectasia. (b) An ulcerating BCC on the lower eyelid. (c) A recurrent morphoeic BCC ((a) and (b) courtesy of Mr AR Greenbaum; (c) courtesy of St John's Institute for Dermatology, London, UK).

Mohs' micrographic surgery is performed under local anaesthesia (which is one of its limitations) and involves an initial 'saucerising excision' of the primary tumour's gross extent. The sample and the defect are then marked and orientated. A map of the specimen is drawn and characterised using different coloured stains in different quadrants. A histotechnician and a Mohs' surgeon work together, whereby the histotechnician sections the tissue horizontally (including lateral and deep margins

Figure 42.40 A basaloid, epithelial tumour with palisading cells on the periphery of the tumour that sits within a mucinous stroma (courtesy of Dr Catherine di Stefanato, Consultant Dermatopathologist, St John's Institute for Dermatology, London, UK).

in the same slide) and stains it with haematoxylin and eosin. The Mohs' surgeon then examines the slides for the presence of residual tumour and excises more tissue from the relevant parts of the mapped defect as necessary. In theory, the technique offers complete evaluation of the lateral and deep margins of tumour excision and so should thus be dependable. Complete excision rates exceeding 99 per cent are the rule in trained experienced hands.

In the elderly or infirm patients, radiotherapy produces similar recurrence rates to surgery. Superficial tumours can be treated with topical treatments (5-fluorouracil, imiquimod) or cryotherapy.

Excision must be complete as there is a 67 per cent recurrence rate if margins are grossly involved and a 33 per cent recurrence rate within two years with microscopic involvement or when reported 'close'. Thus, patients with uncomplicated completely excised lesions can be discharged. Follow up is reserved for patients with tumours in high-risk areas, namely globally sun-damaged skin, syndromes (for example naevoid basal cell carcinoma syndrome) and incomplete excisions in patients who have declined further surgery.

Cutaneous squamous cell carcinoma

SCC is a malignant tumour of keratinising cells of the epidermis or its appendages. It arises from the stratum germinatum of the epidermis and expresses cytokeratins 1 and 10.

Epidemiology

SCC is the second most common form of skin cancer. It is four times less common than BCC and affects the elderly. It is strongly related to cumulative sun exposure and damage, and is twice as common in men and in white-skinned individuals living nearer the equator. SCC is also associated with chronic inflammation (chronic sinus tracts, pre-existing scars, osteomyelitis, burns, vaccination points) and immunosuppression (organ

transplant recipients). When an SCC appears in a scar it is known as a Marjolin's ulcer.

The time taken to develop an SCC after radiation exposure is proportional to the wavelength of the radiation. SCC is also caused by chemical carcinogens (arsenicals, tar), and infection with human papilloma virus 5 and 16. There is also evidence that current and previous tobacco use doubles the relative risk of SCC (Summary box 42.5).

Summary box 42.5

Squamous cell carcinoma

- Associated with chronic inflammation
- Invariably ulcerated lesion
- Metastasis in 2 per cent cases

Macroscopic

The appearance of SCC may vary from smooth nodular, verrucous, papillomatous to ulcerating lesions (Figure 42.41). However, all variants will eventually ulcerate as they grow. The ulcers have a characteristic everted edge and are surrounded by inflamed, indurated skin. The differential diagnosis of an SCC are actinic keratosis, BCC, keratoacanthoma, pyoderma gangrenosum and warts.

Microscopic

Characteristic irregular masses of squamous epithelium are noted to proliferate and invade the dermis from the germinal layer (Figure 42.42). This tumour stains positive for cytokeratins 1 and 10. SCC can be histologically graded according to Broders' histological grading. This system describes the proportion of de-differentiated cells (i.e. the ratio of pleomorphic and anaplastic cells:normal cells).

The histopathology report on an SCC should include information on the pathological pattern (e.g. adenoid); the cellular morphology (e.g. spindle); the Broders' grade; the depth of invasion, the presence of any perineural or vascular invasion and the deep and peripheral margin clearance (Table 42.3).

Prognosis

There are several independent prognostic variables for SCC:

- 1 Invasion:
 - a. Depth: the deeper the lesion, the worse the prognosis. For SCC <2 mm, metastasis is highly unlikely; whereas if >6 mm, 15 per cent of SCCs will have metastasised.
 - b. Surface size: lesions >2 cm have a worse prognosis than smaller ones.
- 2 Histological grade: the higher the Broders' grade, the worse the prognosis.
- 3 Site: SCCs on the lips and ears have higher local recurrence rates than lesions elsewhere and tumours at the extremities fare worse than those on the trunk.
- 4 Aetiology: SCCs that arise in burn scars, osteomyelitis skin sinuses, chronic ulcers and areas of skin that have been irradiated have a higher metastatic potential.

Albert Compton Broders, 1885–1964, an American pathologist of Minnesota, USA and Chairman of the Department of Surgical Pathology, The Mayo Clinic, Rochester, Minnesota, MN, USA; for one year in 1935 Professor of Surgical Pathology and Director of Cancer Research, University of Virginia, VA, USA. Broders graded rectal cancer in the USA in a manner that Cuthbert Dukes classified them in the UK. A combination of Broders' grading and Dukes' classification gave a more accurate prognosis for rectal carcinoma than either method alone.

Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

- 5 Immunosuppression: SCC will invade further in those with impaired immune response.
- 6 Tumours with perineural involvement have a worse prognosis and require a wider than usual clearance.

The overall rate of metastasis is 2 per cent for SCC – usually to regional nodes – with a local recurrence rate of 20 per cent.

Management

SCC is a heterogeneous tumour with a malignant behaviour that varies between subtypes. Management must therefore address the need for definitive treatment, the possibility of in-transit metastasis and the tumour's tendency for lymphatic metastasis.

Surgical excision is the only means of providing accurate histology. The margins for primary excision should be tailored to surface size in the first instance. This should ideally be assessed using surgical loupe magnification. A 4-mm clearance margin should be achieved if the SCC measures <2 cm across, and a 1-cm clearance margin if >2 cm.

Ninety-five per cent of local recurrence and regional metastases occur within five years, thus follow up beyond this period is not indicated.

Cutaneous malignant melanoma

Melanoma is a cancer of melanin producing cells and can therefore arise in skin, mucosa, retina and the leptomeninges.

Epidemiology

Cutaneous melanoma is caused largely by exposure to ultraviolet radiation. Its rise in incidence reflects social behaviour and increased recreational activity in the sun among white-skinned races not suited to sun exposure. Although it accounts for less than 5 per cent of skin malignancy, it is responsible for over 75 per cent of skin malignancy related deaths.

Malignant melanoma (MM) accounts for 3 per cent of all malignancy worldwide. It is the most common cancer in young adults (20–39 years) and the most likely cause of cancer-related death.

Distribution between the sexes varies around the world and reflects occupational and recreational exposure to sunlight. Likewise, geographical distribution reflects exposure of white-skinned individuals to sunlight: Auckland in New Zealand currently reports the highest incidence per capita, and before that Brisbane in Australia held that distinction.

Five per cent of all patients with MM will develop a second

primary melanoma. Seven per cent of MMs present as occult metastases from an unknown primary.

Pathophysiology

UV exposure is the major causal factor for developing MM. Cumulative exposure favours the development of lentigo maligna melanoma (LMM), whereas 'flash fry' exposure – typical of rapidly acquired holiday tans – favours the other morphological variants (Summary box 42.6).

Summary box 42.6

Malignant melanoma

- Rising incidence
- Genetic and acquired risk factors
- Superficial spreading form the most common
- Breslow thickness most important prognostic indicator
- Sentinel node biopsy useful for lymphatic mapping

A small proportion of MMs are genetically mediated, as in xeroderma pigmentosum which increases the relative risk of developing MM to 1000. Immunosuppression secondary to drugs or HIV infection will increase the incidence of MM by 20–30-fold.

The risk factors for developing MM are summarised below:

- Xeroderma pigmentosum (relative risk = 1000)
- Past medical or family history of MM with dysplastic naevi (relative risk = 33–1269)
- Previous melanoma (relative risk = 84)
- High total number of naevi (relative risk = 3.4, if >20 naevi)
- Dysplastic naevi (10 per cent lifetime risk)
- Red hair (relative risk = 3)
- Tendency to freckle (relative risk = 1.9)
- Immune compromised conditions: HIV infection, Hodgkin's disease, cyclosporin A therapy
- Giant congenital pigmented naevus (increased risk)
- History of sunburn – especially in childhood.

Macroscopic

Only 10–20 per cent of MM form in pre-existing naevi, with the remainder arising *de novo* in previously normally pigmented skin. The most likely naevi to form MM are the junctional and compound types.

Macroscopic features in a pre-existing naevus that suggest malignant change are listed in Summary box 42.7.

There are four common macroscopic variants of MM. There are several other notable, but rarer forms.

Summary box 42.7

Macroscopic features in naevi suggestive of malignant melanoma

- Change in size – any adult naevus >6 mm is suspect (for reference a lead pencil diameter is 7 mm) and anything changing to >10 mm is more likely to be malignant than benign
- Shape
- Colour
- Thickness (elevation/nodularity or ulceration)
- Satellite lesions (pigment spreading into surrounding area)
- Tingling/itching/serosanguinous discharge (usually late signs)
- Blood supply: melanomas >1 mm thick have a blood supply which can be found with a hand-held Doppler, so 'Doppler positive' pigmented lesions should be excised

Superficial spreading melanoma

This is the most common type (70 per cent), usually arising in a pre-existent naevus, after several years of slow change, followed by rapid growth in the preceding months before presentation

(Figure 42.43). Typically it is a darker pigmented area in a junctional naevus. Nodularity within superficial spreading melanoma (SSM) heralds the onset of the vertical growth phase.

Nodular melanoma

Nodular melanoma (NM) accounts for 15 per cent of all MM and tends to be more aggressive than SSM, with a shorter clinical onset. These lesions typically arise *de novo* in skin and are more common in men than women, often presenting in middle age and usually on the trunk, head or neck (Figure 42.44). They typically appear as blue/black papules, 1–2 cm in diameter, and because they lack the horizontal growth phase, they tend to be sharply demarcated. Up to 5 per cent are amelanotic.

Lentigo maligna melanoma

Previously also known as Hutchinson's melanotic freckle. This variant presents as a slow-growing, variegated brown macule, on the face, neck or hands of the elderly (Figure 42.45). They are positively correlated with prolonged, intense sun exposure, affecting women more than men. They account for between 5 and 10 per cent of MM. LMM are thought to have less metastatic potential than other variants as they take longer to enter a vertical growth phase. Nonetheless, when they have entered the vertical growth phase their metastatic potential is the same as any other melanoma.

Acral lentiginous melanoma

Acral lentiginous melanoma (ALM) affects the soles of the feet and the palms of the hands. It is rare in white-skinned individuals (2–8 per cent of MM) but is more common in the Afro-Caribbean, Hispanic and Asian populations (35–60 per cent). It usually presents as a flat, irregular macule in later life (Figure 42.46). Twenty-five per cent are amelanotic and may mimic a fungal infection or pyogenic granuloma.

MM under the finger nail is usually SSM rather than ALM. For finger or toe nail lesions it is vital to biopsy the nail matrix rather than just the pigment on the nail plate. A classical feature of a subungual melanoma is Hutchinson's sign. This is nail fold pigmentation which then widens progressively to produce a triangular pigmented macule with associated nail dystrophy. The differential diagnosis is 'benign racial melanonychia', which produces a linear dark streak under a nail in a dark-skinned individual. Malignancy is unlikely if the nail fold is uninvolved.

Miscellaneous

- Amelanotic melanoma (often arising in the gastrointestinal tract and presenting with obstruction, intussusception or as a metastasis from an unknown primary).
- Desmoplastic – mostly found on the head and neck region. It has a propensity for perineural infiltration and often recurs locally if not widely excised. May be amelanotic clinically.

Microscopic

Malignant change occurs in the melanocytes in the basal epidermis, while *in situ*, atypical melanocytes are limited to the dermoepidermal junction and show no evidence of dermal involvement. During the horizontal growth phase, cells spread along the dermoepidermal junction and although they may breach the dermis, their migration is predominantly radial. During the vertical growth phase, the dermis may be invaded.

Figure 42.43 Superficial spreading melanoma (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.44 Nodular melanoma (courtesy of St John's Institute for Dermatology, London, UK).

The greater the depth of invasion, the greater is the metastatic potential of the tumour.

Management

History and clinical examination should be directed at discovering the primary lesion and identification of local, regional or distant spread. Clinical photography is useful when observation is chosen rather than excision biopsy for definitive histopathological diagnosis. An excision biopsy with a 2–5 mm margin of skin and a cuff of subdermal fat is acceptable. Incision biopsy is occasionally indicated – for instance in large lesions on the face where an excision biopsy of the whole lesion would be disfiguring.

Biopsy and pathological examination provide the first step towards staging melanoma. The Breslow thickness of a melanoma (measured to the nearest 0.1 mm from the granular layer to the

Alexander Breslow, 1928–1980, American pathologist. Pathologist, George Washington University, Washington DC, USA, first reported in 1970 that the prognosis depends upon the thickness of the tumour.

Figure 42.45 Lentigo maligna melanoma (courtesy of St John's Institute for Dermatology, London, UK).

base of tumour) is the most important prognostic indicator in the absence of lymph node metastases. The AJCC staging system then takes lymph node and distant metastases into account (see Table 42.4).

Investigations

Guidelines for staging are controversial. One approach is to aim investigations towards detecting occult disease so as to upstage patients and then treat them accurately and appropriately. Thus, offering sentinel node biopsy to patients with clinical stage II disease is prudent, investigations for stage III disease should be directed to individual clinical presentation.

Local treatment

The treatment for melanoma is surgery. Lentigo maligna (melanoma *in situ*) should be excised completely in most clinical situations because of the risk of it entering the vertical growth phase to become LMM. A complete excision requires no further treatment.

Figure 42.46 (a) Acral lentiginous melanoma on the sole of the foot (courtesy of Mr AR Greenbaum). (b) Subungual melanoma – probably a superficial spreading melanoma. Note the swelling proximal to the nail fold. (c) Benign racial melanonychia. ((b) and (c) Courtesy of St John's Institute for Dermatology, London, UK.)

For melanoma <1 mm deep, wide local excision with a 1 cm margin is sufficient. For deeper lesions, a 2 cm margin is recommended as there is no evidence that wider margins make a difference.

Regional lymph nodes

The likelihood of metastatic spread to regional lymph nodes is proportional to the Breslow thickness of the melanoma. Management of regional lymph nodes has been a contentious topic for well over a century. Some advocate simultaneous elective lymph node clearance at the time of wide excision of the primary melanoma. Ideally, one would like to be able to select for treatment those patients with the highest risk of metastatic spread.

Sentinel node biopsy (SNB) is an investigation based on the fact that lymphatic metastasis proceeds in an orderly fashion and can be predicted by mapping the lymphatic drainage from a primary tumour to the first or 'sentinel' node in the regional lymphatic basin. There is negligible benefit in performing SNB in patients whose primary melanoma is thinner than 1 mm. When SNB is performed according to consensus standards, it is predictive of the regional nodal status in 99 per cent of cases. Seventy-five per cent of patients with metastases in the sentinel nodes will have no other involved regional nodes, so while the current standard approach is to proceed to completion lymphadenectomy, this will overtreat a significant number of sentinel node-positive patients. This might appear a better option than potentially undertreating 20–30 per cent of patients with positive sentinel nodes. Evidence of objective survival benefit from SNB is currently unavailable, but several large prospective clinical trials are in progress to investigate this and meanwhile, SNB remains part of the AJCC staging system.

Current treatment for biopsy positive nodal disease is block dissection of regional lymph nodes to remove all the lymph nodes in that regional basin.

Adjuvant therapy

None is of proven benefit, with clinical trials currently looking at vaccine and interferon treatments. Recent promising research has focused on mutations in the *BRAF* gene, which is found in about 60 per cent of malignant melanoma. Drugs which block the products of the faulty gene are currently showing very promising results in clinical trials with evidence that it shrinks metastatic deposits in patients with stage 4 disease.

Prognosis

The Breslow thickness of the primary tumour offers the best correlation with survival in stage I disease. The higher the mitotic index, the poorer is the prognosis of the primary tumour. This has greater significance than the presence or absence of ulceration.

The presence of lymph node metastases is the single most important prognostic index in melanoma; outweighing both tumour and host factors. The number of affected nodes and the presence of extranodal extension are also significant outcome predictors. Once regional nodes are clinically involved, 70–85 per cent of patients will have occult distant metastases.

Merkel cell (dermal mechanoreceptor) tumour

This is an aggressive malignant tumour of Merkel cells (Figure 42.47). It usually affects the elderly and is four times more

common in women than men. Treatment is with wide local excision aiming for a 25–30-mm margin, followed by radiotherapy.

VASCULAR LESIONS

Congenital: haemangiomas and vascular malformations

These can be subclassified biologically into vascular tumours or vascular malformations based on their endothelial characteristics; or radiologically into haemangiomas, vascular and lymphatic malformations based on their vascular dynamics.

Haemangiomas

These are benign endothelial tumours that affect three girls for every boy. Thirty per cent have a herald patch at birth, which then grows rapidly in the first year of life, then slowly involutes over several years with 70 per cent having resolved by seven years of age. Large haemangiomas can trap platelets leading to thrombocytopenia (Kasabach–Merritt syndrome).

Vascular malformations

Vascular malformations affect boys and girls equally and are associated with numerous syndromes. They are invariably present at birth but may be missed if deep to the skin. Vascular malformations subsequently grow in proportion to the child's growth (other than in response to sepsis or hormonal stimulation). Stasis can lead to a localised, consumptive coagulopathy in large venous malformations. Low-flow malformations may cause skeletal hypoplasia, while high flow malformations can cause hypertrophy.

Common vascular birthmarks

Salmon patch

This is a haemangioma that presents as a pinkish macule usually at the nape of neck (Figure 42.48). It is caused by an area of persistent fetal dermal circulation, which usually disappears at one year.

Capillary haemangioma (strawberry naevus)

This is the most common birth mark occurring most commonly on the head and neck (Figure 42.49). Ninety per cent appear at birth, and as a consequence of intravascular thrombosis, fibrosis and mast cell infiltration, 10 per cent resolve each subsequent year, with 70 per cent resolved by seven years of age.

White skin is affected most commonly and girls are affected three times more than boys.

Capillary vascular malformations ('port-wine' stains)

Capillary vascular malformations ('port-wine' stains (PWS)) are 20 times less common than capillary haemangiomas and result from defective maturation of cutaneous sympathetic innervation during embryogenesis leading to localised intradermal capillary vasodilatation (Figure 42.50). They appear at birth as flat, smooth, intensely purple stained areas, most frequently on

the head and neck, often within the maxillary and mandibular dermatomes of the trigeminal nerve.

Treatment with intense pulsed light and pulse dye laser are successful. PWS may be associated with various syndromes listed below:

- Sturge–Weber syndrome: PWS affecting trigeminal dermatomes; associated with epilepsy, glaucoma secondary to ipsilateral, leptomeningeal angiomas, cortical atrophy and visual field defects.
- Klippel–Trenaunay syndrome: PWS on a limb with associated bone and soft tissue hypertrophy and lateral varicose veins when the lower limb is involved. It is called Parkes Weber syndrome if there is an associated arteriovenous malformation.
- Proteus syndrome: PWS and regional gigantism in association with lymphatic (lymphaticovenous) malformation. Hypertrophy is always asymmetrical.

Acquired

Campbell de Morgan spots

These are arteriovenous fistulas at the dermal capillary level in sun exposed skin of older patients (Figure 42.51).

Spider naevi

These are angiomas that appear (and may disappear) spontaneously at puberty or in two-thirds of pregnant women, usually

William Allen Sturge, 1850–1919, physician, The Royal Free Hospital, London, UK.

Frederick Parkes Weber, 1863–1962, physician, The German Hospital, Dalston, London, UK.

Maurice Klippel, 1858–1942, neurologist, La Salpêtrière, Paris, France.

Paul Trenaunay, b. 1875, a French neurologist, Klippel and Trenaunay described the condition as a joint paper in 1900.

Proteus was a minor sea god of Greek mythology, who had the power of prophesy and was able to assume different shapes in order to avoid answering questions.

Campbell Greig de Morgan, 1811–1876, surgeon, the Middlesex Hospital, London UK.

Figure 42.48 Salmon patch (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.49 Capillary haemangioma (courtesy of St John's Institute for Dermatology, London, UK).

disappearing in the puerperium (Figure 42.52). Spider naevi are also associated with chronic liver disease. They can be treated with intense pulsed light or pulse dye laser.

Pyogenic granuloma

These share many histological characteristics of haemangiomas and are probably a subtype thereof (Figure 42.53).

Most are small (0.5–1.5 cm), raised, pedunculated, soft red nodular lesions showing superficial ulceration and a tendency to bleed after trivial trauma. They should be excised with a minimal margin.

Glomus tumour

These arise from subcutaneous arteriovenous shunts (Sucquet–Hoyer canals) especially in the corium of the nail bed. Typically,

Figure 42.50 'Port-wine' stain (courtesy of St John's Institute for Dermatology, London, UK).

Figure 42.51 Campbell de Morgan spot (courtesy of Mr AR Greenbaum).

it is a small, purple nodule measuring a few millimetres in size which is disproportionately painful in response to insignificant stimuli, including cold exposure (Figure 42.54). Subungual varieties may be invisible causing paroxysmal digital pain.

Angiosarcoma ('malignant angioendothelioma')

Angiosarcoma is a rare, highly malignant tumour arising from the endothelial cells (Figure 42.55). The lymphangiosarcoma variant arises from lymphatic endothelium and can develop in lymphoedematous tissue, particularly an extremity. Proliferation is rapid with early systemic spread.

Kaposi's sarcoma

This is a malignant, proliferative tumour of vascular endothelial cells, which was first described in elderly Jewish men, but is now most commonly associated with immune compromise after transplantation or HIV infection (Figure 42.56). There appears to be a causal link with infection by human herpes virus 8. Kaposi's sarcoma usually starts as a red brown, indurated, plaque-like skin lesion that becomes nodular and then ulcerates. Treatment is with radiotherapy.

WOUNDS: CONGENITAL

Cutis aplasia congenita

A rare condition characterised by the congenital absence of epidermis, dermis and, in some cases, subcutaneous tissues, with underlying bony defects in 20 per cent. Lesions may occur on any body surface, but localised scalp agenesis is most frequent.

Treatment depends on the severity of the presentation, but usually involves plastic surgery.

Parry-Romberg disease

An uncommon and poorly understood progressive, hemi-facial atrophy of skin, soft tissue and bone. Its incidence is unknown and its inheritance uncertain, but it affects women more commonly than men.

It commonly starts in a patient's late 20s, but can present in

Figure 42.56 Kaposi's sarcoma (courtesy of St John's Institute for Dermatology, London, UK).

Caleb Hillier Parry, 1755–1822, physician, The General Hospital, Bath, UK.

Moritz Heinrich Romberg, 1795–1873, a German neurologist who was Director of the University Hospital, Berlin, Germany.

childhood, when the resulting deformity is worse because it is magnified by differential growth elsewhere. The most common presentation is confined to lipodystrophy, but mixed atrophy of skin, fat, muscle, cartilage and bone combined result in the classic 'Coup de Sabre' deformity.

The condition is self-limiting, usually by 5–10 years after onset. Once the condition is stable, plastic surgical techniques can be employed alone or in combination to reconstruct an aesthetic contour.

Spina bifida

Failure of closure of the caudal neuropore during the fourth week *in utero* results in incomplete development of some or all of the structural elements posterior to the spinal cord. This can occur anywhere, but is most common in lumbar vertebrae and presents as gross variants: spina bifida occulta in which there is a bony defect without neural protrusion and spina bifida cystica, in which there is herniation of the meninges (meningocoele); spinal cord (myelocoele) or, most commonly, both (menigo-myelocoele) and therefore, asymptomatic. Management ideally involves a multidisciplinary approach and is directed towards protecting the spinal cord, preventing cerebrospinal fluid contamination and secondary hydrocephalus and meningitis.

WOUNDS: ACQUIRED

Pressure sores

These begin with tissue necrosis at a pressure point (next to a bony prominence) and develop into a cone shape volume of necrotic loss (with the cone's tip superficial). As many as 10 per cent of acute hospital inpatients will suffer some degree of pressure sores. The majority affect the elderly and patients with

spinal injury or decreased sensibility; 80 per cent of paraplegics will get a pressure sore and 8 per cent die as a result.

The pathogenesis of pressure sores revolves around unrelieved pressure: an increase in local tissue pressure above that of perfusion pressure produces ischaemic necrosis that is directly proportional to the duration and degree of pressure and inversely proportional to the area over which it is applied. Muscle and fat are more susceptible to pressure than skin.

In a patient who has no predisposing factors (who developed a sore while unable to move, but normally can move), management is aimed at debridement and repair of the defect on the assumption that recurrence will not occur once normal function and sensibility returns. In the paraplegic, recurrence is likely, so management should involve a multidisciplinary approach with surgery used sparingly once all other predisposing factors have been addressed. Primary treatment involves relieving pressure (special mattress; nursing care; relief of muscle spasm and contractures); optimising nutrition; correcting anaemia; preventing infection and dressings. Surgery involves thorough debridement to promote healing and plastic surgery to reconstruct the defect.

LEARNING OBJECTIVES

- To review the pathophysiology of raised intracranial pressure (ICP) and to incorporate an understanding of hydrocephalus
- To recognise common presentations of intracranial infection, and know the principles of management
- To appreciate the spectrum of common brain tumours, their presentation, investigation and treatment
- To be familiar with common developmental and other pathologies encountered in paediatric neurosurgical practice
- To understand the indications and approaches available for the management of epilepsy, pain syndromes and movement disorders
- To be aware of other pathology which may be addressed by neurosurgeons, including occlusive vascular disease and peripheral neuropathies
- To note key practical and ethical issues affecting the practice of neurosurgery, including risks of craniotomy, complication rates, Creutzfeldt–Jakob disease (CJD) infection and diagnosis of brainstem death

PRINCIPLES OF PATHOPHYSIOLOGY

Raised intracranial pressure

The pathophysiology of raised intracranial pressure (ICP) is addressed in Chapter 25. In summary, when expanding masses exhaust the limited compensation within the rigid cranium, the Monro–Kellie doctrine predicts a rapid increase in pressure, culminating in compromised perfusion and fatal brainstem herniation (see Chapter 25, Figure 25.2).

In the elective context, masses such as tumours produce raised intracranial pressure directly through their own mass effect, and indirectly through surrounding oedema and obstruction of cerebrospinal fluid (CSF) drainage. Patients may complain of pressure headache, worse in the morning and provoked by bending, lying or straining. Nausea, vomiting and visual disturbance are also early features. Later the mass effect will result in drowsiness and lethargy, and ultimately coma.

Examination may reveal a cranial nerve palsy due to compression. Papilloedema (Figure 43.1) develops slowly, so is not a reliable sign of acute raised ICP.

Parinaud's syndrome results from dorsal midbrain compression, and its features include a loss of upgaze known as 'sun-setting' (Figure 43.2). In infants, the fontanelle is tense and bulging, with an increase in head circumference and bulging scalp veins.

Although the presentation may be subacute, raised ICP requires urgent evaluation and management: delay risks progression to cerebral herniation (see Chapter 25, Figure 25.2) result-

ing in neurological deficit and death, vision may also deteriorate rapidly and irreversibly (Summary box 43.1).

Summary box 43.1

Raised intracranial pressure

Acutely raised ICP is a neurosurgical emergency. The symptoms are:

- headache
- nausea and vomiting
- diplopia and blurred vision
- drowsiness then coma

Cerebral oedema

Cytotoxic oedema represents neuronal and glial swelling in response to insults such as ischaemia. Vasogenic oedema, by contrast, represents fluid accumulation in the extracellular spaces as a result of capillary leak and breakdown of the blood–brain barrier. It is commonly seen around tumours.

Hydrocephalus

Hydrocephalus refers to an increase in CSF volume and ventricular enlargement due to disturbance of production, flow or reabsorption of CSF.

The total CSF volume is normally about 150 mL. Production from the walls of the ventricles and the choroid plexus is about 20 mL/hour. CSF flows from the lateral ventricles through

the foramina of Monro to the third ventricle, then down the cerebral aqueduct to the fourth ventricle, where it exits to the subarachnoid space via the midline foramen of Magendie and the lateral foramina of Luschka (Figure 43.3). CSF is reabsorbed into the arachnoid villi along the superior sagittal sinus.

Hydrocephalus may result from an excess of CSF production (in the rare condition of choroid plexus papilloma), from obstruction to circulation (an obstructive hydrocephalus) and from failure of reabsorption (a communicating hydrocephalus) (see Figures 43.4, 43.5 and 43.6). Hydrocephalus ex vacuo describes the ventriculomegaly associated with brain atrophy. Causes of hydrocephalus are listed in Table 43.1.

Disorders of CSF flow with poorly understood pathogenesis manifest in two syndromes, normal pressure hydrocephalus and idiopathic intracranial hypertension (IIH).

1 Normal pressure hydrocephalus. This is an important cause of dementia since it is readily reversible. It typically presents in older patients with the triad of gait disturbance, incontinence and cognitive decline. It may occur *de novo* or on a background of previous brain insults including subarachnoid haemorrhage (SAH), head injury, meningitis and tumour.

Figure 43.3 'CSF pathways'. Cerebrospinal fluid (CSF) is produced by the choroid plexus of the lateral ventricles, and flows through the foramina of Monro into the midline third ventricle, then through the cerebral aqueduct to the fourth ventricle, before exiting through the foramina of Magendie and Luschka to the subarachnoid space around the brain.

Table 43.1 Aetiology of hydrocephalus.

Obstructive hydrocephalus	Lesions within the ventricle
	Lesions in the ventricular wall
	Lesions distant from the ventricle but with a mass effect
Communicating hydrocephalus	Post-haemorrhagic
	CSF infection
	Raised CSF protein
Excessive CSF production (rare)	Choroid plexus papilloma/ carcinoma

CSF, cerebrospinal fluid.

Ventriculomegaly is evident on imaging, although this is also seen in the context of cortical atrophy due to other dementia pathologies. The CSF pressure at lumbar puncture (LP) is typically normal, but it is believed that intermittent elevations in pressure may be involved in the aetiology. Lumbar infusion testing involves insertion of a fine drain at lumbar puncture, followed by measurement of the CSF pressure changes associated with a fluid challenge administered through this. This allows evaluation of the likely benefit from definitive treatment by shunt insertion.

2 Idiopathic intracranial hypertension. This condition presents with features of raised ICP without an underlying tumour, explaining the old terms for the condition, pseudotumour cerebri or benign intracranial hypertension. This description is misleading, since IIH can progress rapidly to blindness. The patient, typically a young overweight female, describes a headache typical of raised pressure, and visual deterioration.

Figure 43.4 Pathological specimen of a hydrocephalic brain.

Examination may reveal papilloedema, and occasionally cranial nerve palsies. Imaging is unremarkable, but lumbar puncture demonstrates a raised opening pressure >25 mmHg. The diagnosis is one of exclusion, and the aetiology is not well understood. Impaired CSF resorption may reflect raised venous pressure, either as a result of sinus thrombosis, or secondary to raised intra-abdominal pressure in obese patients. Weight loss and cessation of certain medications including the oral contraceptive pill is often effective. This is combined with medical therapy.

Chronic compensated hydrocephalus is also commonly seen after craniotomy with breach of the ventricles, manifesting as failure to progress or with an overt CSF leak (Summary box 43.2).

Summary box 43.2

Hydrocephalus

- Hydrocephalus describes an increase in CSF volume and ventricular enlargement, often resulting in symptoms of raised ICP
- It may occur as a result of a physical blockage (obstructive hydrocephalus) or due to failure of normal reabsorption (communicating hydrocephalus)

Investigation of raised intracranial pressure

Where raised ICP is suspected, computed tomography (CT) is a first-line investigation to demonstrate hydrocephalus, underlying pathology and to evaluate the degree of mass effect and the patency of the basal cisterns, the spaces surrounding the brainstem. This is key to management since lumbar puncture in the setting of raised intracranial pressure can result in downward herniation of brain structures to replace the fluid drained (Chapter 25, Figure 25.2). Many pathologies, as well as the anatomy relating to potential treatments such as third

Figure 43.5 Pineal region tumour (arrow) causing obstructive hydrocephalus.

Figure 43.6 Axial computed tomography scan, showing a neonate with hydrocephalus and markedly dilated ventricles. The temporal horns (arrows), normally just visible, are particularly enlarged.

Figure 43.7 The intracranial pressure waveform: The P1 (percussion wave) corresponds to arterial pulsation. Pathologies including normal pressure hydrocephalus and traumatic injury are associated with a prominent P2 (tidal wave), representing reduced brain compliance.

ventriculostomy, may be better visualised on magnetic resonance imaging (MRI).

Lumbar puncture in obstructive hydrocephalus risks herniation of the brainstem and cerebellar tonsils due to the resulting differential pressure changes (sometimes termed 'coning'). For communicating hydrocephalus, lumbar puncture is of diagnostic value, deriving an opening pressure and assessment of the CSF contents. It is also therapeutic – drainage of typically between 10 and 30 mL of CSF, with the goal of halving the opening pressure, can relieve the hydrocephalus at least temporarily.

Lumbar infusion testing involves insertion of a lumbar drain into the thecal sac, then infusion of saline and pressure measurement to establish the resistance to CSF outflow. For example, in the case of normal pressure hydrocephalus, values greater than 14 mmHg/mL per minute can be taken to imply compromised resorption and the potential for good response to shunt insertion.

Continuous intracranial pressure monitoring using an ICP bolt as for head injury may be of value when the diagnosis is in doubt (see Figure 43.7 and Summary box 43.3).

Summary box 43.3

Investigation of raised ICP

- CT is the first line of investigation
- LP can confirm raised ICP and relieve it temporarily, but only after review of the CT to exclude a mass lesion or obstructive hydrocephalus, which might lead to 'coning' at LP

Management

Acute hydrocephalus is an emergency since the condition can progress over minutes or hours to coma and death. It may be relieved by addressing the underlying pathology, for instance by excision of a tumour responsible for an obstructive hydrocephalus. Most often, however, temporary ventricular drainage is required, either as an emergency in an obtunded or deteriorating patient, or as a precaution during definitive surgery considering the possibility for postoperative swelling.

Figure 43.8 Various types of cerebrospinal fluid shunt.

External ventricular drain

External ventricular drains (EVDs) are an effective temporary measure to relieve hydrocephalus. Most commonly they are inserted freehand to the right of midline, anterior to the coronal suture, so that the catheter tip rests adjacent to the foramen of Monro in the lateral ventricle. The catheter is then connected to a drain set such that CSF drains when the ventricular pressure exceeds a threshold typically set at 10–20 mmHg. Intrathecal antibiotics may also be delivered through the EVD.

Ventriculoperitoneal shunts

Ventriculoperitoneal (VP) shunting comprises insertion of a ventricular catheter, which may be antibiotic impregnated, into the frontal or occipital horn of the lateral ventricle, while a distal catheter is tunnelled subcutaneously to the abdomen. Ventriculoatrial and ventriculopleural shunting is also possible. A shunt valve, with an opening pressure which may be high, medium or low, is inserted at the junction of these catheters (see Figure 43.8). Selection of the shunt valve is a balance and must be tailored to each patient: high pressure valves may fail to allow adequate CSF drainage, whereas low pressure valves can overdrain (see below). Flow regulated valves incorporate mechanisms to maintain relatively constant rates of drainage despite a range of pressures across the valve. Other valves feature different opening pressures depending on position, preventing overdrainage on standing for instance. Programmable valves can be adjusted magnetically using a device applied externally over the valve. Valves also typically incorporate a CSF reservoir which allows for sampling.

Shunt complications

Overdrainage can result in low-pressure headaches, which are typically worse on standing. Collapse of the ventricles can cause accumulation of fluid in the subdural space, a subdural hygroma, or bleeding producing a subdural haematoma. The slit ventricle syndrome describes the situation in children treated with shunts, whose ventricles and subarachnoid spaces are underdeveloped, resulting in poor brain compliance. In these patients normal fluctuations in ICP are exaggerated so that coughing and straining may cause symptoms of raised ICP. Any shunt blockage may not be evident on scan as the ventricles fail to enlarge.

Shunts are vulnerable to infection and to blockage, so that 15–20 per cent require replacement within three years. Seventy-five per cent of infection presents within one month, a result of introduction at the time of insertion. Risk factors include very young patients, open myelomeningocele, long operation time and staff movement in and out of theatre. The shunt is removed, and external CSF drainage or serial LP instituted to cover a course of antibiotic therapy. Once CSF sampling confirms resolution of the infection and a normal protein concentration, a shunt can be inserted at a new site.

The majority of blockages are attributable to cellular and proteinaceous debris especially due to infection, but choroid plexus adhesion or blood clot may also be responsible.

Endoscopic third ventriculostomy

This procedure is especially useful in obstructive hydrocephalus due to aqueduct stenosis. A neuroendoscope is inserted into the frontal horn of the lateral ventricle and then into the third ventricle via the foramen of Monro. The floor of the ventricle is then opened between the mamillary bodies and the pituitary recess. Free drainage between the third ventricle and the adjacent subarachnoid cisterns is then possible, without the infection risk posed by implanted tubing. Reblockage of this route is common, however, and many patients will subsequently require a shunt. Rare but serious complications include damage to the basilar artery, or damage to the fornix resulting in permanent memory impairment (Summary box 43.4).

Summary box 43.4

Treating hydrocephalus

- Temporary CSF diversion can be achieved with an EVD
- In the long term a shunt, usually connecting the lateral ventricles with the peritoneal cavity in the abdomen (VP shunt), is the mainstay of management
- Shunt blockage and infection are common complications

INTRACRANIAL INFECTION

Meningitis and ventriculitis

Meningitis describes inflammation of the meninges of the brain and spinal cord, most commonly and most seriously due to bacterial infection.

Community-acquired bacterial meningitis typically presents with fever, meningism (headache, neck stiffness and photophobia) and deterioration in conscious level. The natural history involves a rapid progression to subpial encephalopathy, venous thrombosis, cerebral oedema and death. Therefore empirical intravenous antibiotic therapy should be commenced as soon as the diagnosis is suspected. Urgent lumbar puncture is required to confirm the diagnosis and ultimately to guide treatment. Since the differential diagnosis of this presentation includes abscess, empyema and subarachnoid haemorrhage, initial CT imaging, where available immediately, is desirable to confirm that lumbar puncture is necessary and safe. A 2007 Cochrane review demonstrated improved mortality and neurological outcome associated with administration of steroids (dexamethasone 0.15 mg/kg up to 10 mg four times daily for 4 days).

The common organisms responsible for spontaneous bacterial meningitis are *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis*, the latter occurring in sporadic outbreaks. Neonates are susceptible to group B streptococcus, *Escherichia coli* and *Listeria*.

Meningitis in the context of surgery typically follows a more insidious course, but nonetheless remains a feared complication requiring prompt intervention. Typical organisms are *Staphylococcus aureus*, Enterobacteriaceae, *Pseudomonas* and *Pneumococci*.

Meningitis after head injury is common, affecting 25 per cent of patients with base of skull fracture and CSF leak. Repair of the CSF leak may be required, and empirical antibiotics should have activity against commensal nasal organisms including Gram-positive cocci and Gram-negative bacilli in the presence of symptoms/signs of clinical meningitis.

Ventriculitis refers to infection in the ventricles, commonly as a complication of meningitis or due to contamination from a shunt or external drain. Where a drain is present, treatment may include administration of intrathecal antibiotics through it (Summary box 43.5).

Summary box 43.5

Meningitis

- A feared complication of neurosurgery and of head injury
- Clinical diagnosis is supported by CT to exclude other pathology
- CSF samples are taken for glucose and protein assay, and for microscopy and culture
- Treatment, pending identification of an organism, is with broad-spectrum antibiotics

Brain abscess and empyema

Abscesses arise when the brain is exposed directly, for example as a result of fracture or infection of an air sinus, or at surgery. They also result from haematogenous spread, typically in association with respiratory and dental infections, or endocarditis. In 25 per cent of cases, no underlying primary infection is found. The organisms involved are normally bacteria, but immunocompromised hosts in particular are vulnerable to a broad range of pathogens:

- sinus/mastoid infection: aerobic and anaerobic Streptococci; Bacteroides; Enterobacteria; Staphylococci; Pseudomonas;
- haematogenous spread: Bacteroides; Streptococci;
- penetrating trauma: *Staphylococcus aureus*; Clostridium; Bacillus; Enterobacteria;
- food contamination: toxoplasma, pork tapeworm (producing neurocysticercosis);
- immunocompromise e.g. HIV/AIDS: protozoal (e.g. toxoplasma), fungal (e.g. Cryptococcus), viral (e.g. JC virus producing multifocal leukoencephalopathy) and mycobacterial abscesses are encountered.

Early cerebritis (day 3–5) is characterised by neutrophil infiltration (Figure 43.9). This progresses to a late cerebritis with necrosis, oedema and macrophage recruitment (day 5–14) (Figure 43.10). After this the abscess is walled off by a developing collagenous capsule which matures over weeks and months.

Figure 43.9 Axial computed tomography scan with contrast of a patient with frontal sinusitis and epilepsy, showing a hypodense area of cerebritis in the left frontal region.

Diagnosis

Patients present with the triad of features associated with mass lesions; these are focal deficits, seizures and raised ICP. A typical history might include fever and malaise, progressing over hours or days to drowsiness and confusion, then focal weakness or seizure. Low-grade pyrexia and equivocal blood markers of inflammation are typical; blood cultures should be obtained at an early stage. CT scan with contrast is the initial imaging modality of choice, and this will demonstrate a well-defined ring-enhancing mass (i.e. the edge enhances on the post-contrast images), typically with a thin smooth wall. The distinction between abscess and tumour can be difficult and has important management implications, since abscesses generally require urgent drainage. Diffusion-weighted MRI is a valuable tool in this context (see Figure 43.11).

Management

The mainstay of management of bacterial abscesses is early surgical drainage, involving needle aspiration through a burrhole with or without image-guidance, or by craniotomy. Intravenous antibiotic therapy is then commenced, using broad-spectrum agents initially then tailoring to the sensitivity of organisms cultured. Treatment should last at least 6 weeks, but a switch to oral therapy may be appropriate after an interval and in consultation with microbiology. Mortality with prompt treatment is about 4 per cent, but if the abscess is allowed to rupture into a ventricle mortality it is over 80 per cent. Up to 50 per cent of patients with brain abscess will develop seizures at some stage, so that prophylactic anticonvulsants should be considered (Summary box 43.6).

Figure 43.10 Axial computed tomography scan with contrast of the same patient as in Figure 43.9 but 2 weeks later. A ring-enhancing lesion has developed, typical of a pyogenic abscess.

Summary box 43.6

Brain abscesses

- Presenting features are those of infection and of intracranial mass lesion
- Imaging reveals a 'ring-enhancing lesion', with tumour usually the main differential
- Early diagnosis, usually followed by drainage, is key for good outcome

Subdural empyema

Subdural empyema refers to an infective collection in the subdural space and may develop as a result of sinusitis, mastoiditis or meningitis, and can complicate trauma or surgery. Figure 43.12 shows a subdural empyema associated with osteomyelitis of the frontal bone and associated scalp swelling, a 'Pott's puffy tumour'. In empyema, pus will generally collect in the parafalcine region and over the convexity, triggering inflammation and thrombosis in the cortical veins which helps to explain the high mortality of 8–12 per cent. Presentation mimics that of meningitis and cerebral abscess; typical CT appearances are of hypodense or isodense subdural collection, with contrast enhancement at the margins, and a degree swelling and midline shift. The empyema may be difficult to visualise, especially on non-contrast CT. Given the risk of herniation, LP should not be performed.

Figure 43.11 The right frontal lesion evident on T2 magnetic resonance imaging (MRI) (main image) exhibits high signal on DWI MRI sequences (top right inset) indicative of restricted diffusion suggestive brain abscess.

Craniotomy or craniectomy allows drainage of the collection and relieves raised ICP and is the treatment of choice. Burrhole drainage, and occasionally intravenous antibiotics without surgical intervention, may also be considered (Summary box 43.7).

Summary box 43.7

Subdural empyema

- Presenting features are similar to those of meningitis or cerebral abscess
- Typically a crescentic collection with a contrast-enhancing rim is evident on CT
- Drainage is the mainstay of treatment

Tuberculosis

Tuberculosis (TB) infection of the central nervous system (CNS) is believed to represent haematogenous spread from primary pulmonary foci. A high index of suspicion is required, especially when population or individual risk factors are present. TB can result in a diverse but overlapping spectrum of pathology, including in the head:

- Tuberculous meningitis – this commonly affects young children; CT demonstrates intense meningeal enhancement, and hydrocephalus is a common sequel.
- Tuberculoma – discrete tumour-like granulomas at the base of the cerebral hemispheres, presenting with mass effect.

Percival Pott, 1714–1788, surgeon, St Bartholomew's Hospital, London, UK, described the 'Puffy Tumour' in 1760. In 1756 he sustained a broken leg after a fall from his horse. As he lay on the ground, he sent a servant to buy a door which acted as a stretcher. While his surgeons were contemplating amputating his leg, he persuaded them to splint the leg instead as a result of which he recovered completely. Although some think that Pott's fracture of the ankle was described after this injury of his, it is not so. He sustained a compound fracture of the femur. Pott was the first to link an environmental factor to the aetiology of cancer when he demonstrated that chimney sweeps developed squamous cell scrotal cancer.

Figure 43.12 Axial computed tomography scan with contrast showing a right hemisphere subdural empyema (short arrow) and a right frontal Pott's puffy tumour (long arrow) (osteomyelitis of the frontal bone).

- Tuberculous abscess – seen predominantly in immunocompromised hosts, this represents progression of a tuberculoma with prominent central caseating necrosis.
- Miliary tuberculosis – describes a diffuse distribution of multiple small tuberculomas through brain substance.

Where the meninges are involved, lymphocytes can be expected to predominate in the CSF, rather than the polymorphs seen with other bacterial meningitides. The increase in protein content and reduction in glucose concentration are also less marked. Ziehl–Neelsen staining for mycobacteria is frequently negative, and polymerase chain reaction (PCR) testing offers relatively rapid diagnosis compared to culture for acid-fast bacilli which may take weeks. A 20–30 mL CSF sample allows spinning to increase the culture yield.

Management is with anti-tuberculous therapy; hydrocephalus may require shunt insertion.

BRAIN TUMOURS

The term 'brain tumour' applies to a wide array of pathologies, detailed in the extensive World Health Organization (WHO) classification. Many are malignant, but even histologically benign tumours may carry a grave prognosis where they encroach on key structures which also limit surgical access. The most common brain tumour is a metastasis. Primary brain tumours represent 1.5 per cent of all cancers, with an incidence

Table 43.2 World Health Organization classification of brain tumours.

Neuroepithelial tumours	Glioma	Astrocytomas Oligodendrogliomas Ependymoma Choroid plexus tumour
	Pineal tumours	
	Neuronal tumours	Ganglioglioma Gangliocytoma Neuroblastoma
	Medulloblastoma	
Nerve sheath tumours	Vestibular schwannoma	
Meningeal tumours	Meningioma	
Pituitary tumours		
Germ cell tumours	Germinoma Teratoma	
Lymphomas		
Tumour-like malformations	Craniopharyngioma Epidermoid tumours Dermoid tumour Colloid cyst	
Metastatic tumours		
Contiguous extension from regional tumours, e.g. glomus tumour		

of 19 per 100 000 person years. Nevertheless, many, especially glial tumours, present commonly in younger age groups and are incurable, so that they account for disproportionate morbidity and mortality.

Classification

The WHO classifies primary brain tumours on the basis of cell of origin and histological grade (Table 43.2).

The common primary brain tumours are gliomas, meningiomas (15–20 per cent of total), pituitary adenomas (10–15 per cent of total) and vestibular schwannomas.

Grade 1 is applied to 'benign' lesions, while grade 4 implies high grade malignancy.

Aetiology

The common primary brain tumours mentioned above occur sporadically. There is no proven risk due to environmental factors, except for radiation exposure, but genetic abnormalities may also predispose (see Table 43.3).

Presentation

Most tumours present with one or more features belonging to three cardinal categories: these are seizure, raised ICP and focal neurological deficit. Pituitary adenomas may also present with endocrine disturbance.

Seizures

Seizures are a common presenting feature, especially of low-grade gliomas arising in the cortical hemispheres. Simple partial seizures, involving focal twitching or similar with preserved consciousness, are the rule, but temporal location will commonly

Table 43.3 Chromosomal abnormalities associated with brain tumours.

Syndrome	Gene defect	Tumour
Neurofibromatosis type 1	Neurofibromin (Chr 17)	Astrocytomas; neurofibromas
Neurofibromatosis type 2	Schwannomin (Chr 22)	Acoustic neuromas (bilateral); meningiomas
Cowden's disease	PTEN (Chr 10)	Astrocytomas
Hereditary non-polyposis colorectal cancer	Multiple	Astrocytomas
Li-Fraumeni syndrome	p53 (Chr 17)	Astrocytomas

produce complex partial seizures, and any seizure may progress to a secondary generalised tonic-clonic fit.

Patients who have had a seizure should be started on an anti-epileptic drug, usually phenytoin or carbamazepine. Therapeutic levels of phenytoin can be achieved rapidly with i.v. loading, but its enzyme-inducing effect can complicate the administration of chemotherapy. Routine prophylaxis in patients with tumours who have no history of seizures is not recommended, although a short course at the time of craniotomy for tumour excision may be warranted.

Raised intracranial pressure

Headache is a presenting feature in only about 50 per cent of patients. It is classically worse in the morning and on straining,

Table 43.4 Patterns of deficit generally associated with certain tumours.

Tumour location	Expected deficit
Pituitary (e.g. pituitary adenoma)	Bitemporal hemianopia; gaze palsies
Cerebellopontine angle (e.g. vestibular schwannoma)	Hearing loss; balance disturbance; tinnitus
Anterior skull base (e.g. olfactory groove meningioma)	Anosmia; ipsilateral optic atrophy; contralateral papilloedema (Foster-Kennedy syndrome)
Occipital (e.g. glioma, metastasis)	Homonymous hemianopia with central sparing
Parietal (dominant hemisphere)	Acalculia; agraphia; left-right disorientation; finger agnosia (Gerstmann syndrome)
Parietal (e.g. glioma)	Sensory inattention; dressing apraxia; astereognosis
Temporal (e.g. glioma)	Memory disturbance; contralateral superior quadrantanopia; dysphasia (dominant hemisphere)
Frontal (e.g. glioma)	Personality change; gait disturbance; urinary incontinence
Brainstem (e.g. brainstem glioma)	Multiple cranial nerve deficits; long tract signs; nystagmus
Posterior fossa (e.g. medulloblastoma)	Ataxia; hydrocephalus

and is accompanied by nausea and vomiting. Pressure effect develops due to tumour mass effect and surrounding oedema, especially in fast-growing metastases and high-grade gliomas (see above under Raised intracranial pressure). Where the differential diagnosis of abscess can be confidently excluded (see above under Brain abscess and empyema), mass effect is controlled initially using high-dose glucocorticoids (e.g. dexamethasone) to reduce swelling. Acute deterioration in this group may represent a developing obstructive hydrocephalus due to compression of CSF drainage pathways (see above under Hydrocephalus), a neurosurgical emergency.

Focal neurological deficit

A focal deficit progressive over time, as opposed to the sudden onset of a vascular accident, is suspicious of tumour. Lesions generally produce characteristic deficits due to local pressure effect, and reflecting location (See Table 43.4 and Summary box 43.8).

Summary box 43.8

Brain tumours

Most brain tumours will present with one or more feature related to the following triad:

- raised ICP
- seizures
- focal deficit

Common brain tumours

Cerebral metastases

Cerebral metastases (Figure 43.13) are the most common intracranial tumours, and affect about one-quarter of cancer sufferers. The tumours of origin and their contribution to the burden of cerebral metastases is detailed in Table 43.5. In general, patients with multiple cerebral metastases are not suitable for surgery. Occasionally, diagnostic biopsy may be warranted where the

primary is unknown. In patients with good functional status and well-controlled systemic disease, craniotomy for resection of a single metastasis, and exceptionally up to three metastases, may be considered.

Glioma

These are tumours of glial cell origin, with subtypes including astrocytomas, oligodendrogliomas, ependymomas and mixed tumours. The diagnosis is histological, but imaging often predicts both a glial origin and the grade of tumour (Figure 43.14): MRI with and without contrast is the preferred modality. If the diagnosis is in doubt, a whole-body CT scan and liver function tests may be required to help exclude an extracranial primary. Initial management should generally include steroids to alleviate any mass effect, and anti-epileptics where seizures are a presenting feature, or are likely in view of temporal location. Definitive treatment depends on the likely tumour grade in view of presentation and imaging findings. Gliomas, except for the grade I pilocytic astrocytoma which typically occurs in children, are notable for their diffuse infiltration into surrounding brain, so that recurrence after even macroscopically complete resection is the rule.

Low grade glioma (WHO Grade II) has a peak incidence in the fourth decade of life. Historically a 'watch-and-wait' strategy, with or without initial biopsy to confirm the diagnosis, has been applied. This reflects the natural history of progression to high grade tumour over a variable period, usually several years. The alternative, now more generally favoured, approach is to pursue initial complete macroscopic resection where feasible. However, this is based on limited evidence that progression is delayed and survival prolonged by this approach. Where tumours encroach on eloquent cortex, especially the speech areas of the dominant hemisphere, awake craniotomy allows mapping of function with surface electrodes at operation, to limit resection and minimise postoperative deficit.

High grade gliomas include anaplastic astrocytomas (WHO grade III) and glioblastomas (WHO grade IV), the most common glial tumour (Figure 43.15).

Figure 43.13 T1 magnetic resonance imaging (MRI) with contrast – two right occipital lung metastases are demonstrated. They are well demarcated and enhance with gadolinium contrast.

Table 43.5 Tissue of origin for brain metastases (approximate).

Origin	Percentage
Lung	40
Breast	15
Melanoma	10
Renal/GU	10
Other Unknown	25

They present *de novo* with peak incidence in the fifth and sixth decades of life respectively, or may represent transformation of previously diagnosed, or clinically silent, low grade gliomas. Active treatment consists of maximal resection, high-dose-focused radiation therapy, and chemotherapy administered locally as carmustine wafers at the time of resection, or systemically with oral temozolomide. Median survival for glioblastoma remains just over 12 months.

Solitary metastasis represents a differential diagnosis for many gliomas, so that a chest x-ray is an important component of the work-up, and if the diagnosis is in significant doubt a whole-body CT and liver function tests to exclude an extracranial primary are required.

Meningioma

Meningiomas are usually benign lesions, although anaplastic variants do occur. They arise from the meninges, and typically present due to mass effect from the tumour, compounded by vasogenic oedema in the adjacent brain and obstructive hydrocephalus where CSF drainage is impaired. Imaging will demonstrate a contrast-enhancing mass distinct from the brain with a dural base (Figure 43.16).

These are generally slow-growing lesions: smaller lesions,

Figure 43.14 Computed tomography (CT) with contrast demonstrates a heterogenous right frontoparietal lesion with mass effect and midline shift, almost certainly a glioblastoma multiforme. A magnetic resonance image with and without contrast will aid evaluation.

perhaps detected incidentally in an elderly patient, may well warrant a 'watch-and-wait' approach. If the lesion is large or positioned so as to impinge on key structures, the patient may require steroids and early surgery. The degree of resection predicts recurrence, with rates of 10 per cent at ten years for total excision with a clear dural margin and 30 per cent at ten years for subtotal excision. Lesions which are difficult to approach surgically may be managed with radiotherapy or stereotactic radiosurgery (Summary box 43.9).

Summary box 43.9

Common brain tumours

- Metastases and gliomas are common tumours arising within brain substance, appearing as 'ring-enhancing' lesions on contrast CT. Surgery is usually life-extending rather than curative
- Meningiomas arise from the meninges around the brain and typically enhance uniformly on contrast CT. Most are benign and amenable to curative resection
- MRI brain is optimal for evaluation of these lesions. Diffusion-weighted sequences help to exclude abscess when glioma or metastasis is suspected
- Where metastasis is suspected, CT of the body may demonstrate the primary lesion and allow staging
- Steroids are administered to control swelling and mass effect in the short term

Pituitary tumours

Most tumours in this region are benign pituitary adenomas, although the differential includes malignant variants, craniopharyngioma, meningioma, aneurysm and Rathke's cleft cyst (Figure 43.17).

Microadenomas are less than 10 mm in size and usually present incidentally or with endocrine effects. Macroadenomas

Figure 43.15 Pathological specimen of a glioblastoma multiforme.

Figure 43.16 On T1 magnetic resonance imaging an extra-axial, durally based lesion is seen to arise in the region of the falx. This is a meningioma.

are larger than 10 mm, and often present with visual field deficits (Figure 43.17). Thirty per cent of adenomas are prolactinomas, 20 per cent are non-functioning, 15 per cent secrete growth hormone and 10 per cent secrete adrenocorticotrophic hormone (ACTH).

Features of note in the initial assessment include any history of galactorrhoea (suggestive of prolactinoma), and Cushingoid or acromegalic features pointing to ACTH- or growth hormone-secreting tumours, respectively. Baseline assessment of pituitary function should include serum prolactin, follicle-stimulating hormone and luteinising hormone together with testosterone in males or oestradiol in females, thyroid function tests, and fasting serum growth hormone and cortisol. Preoperative prolactin levels are crucial since prolactinomas may be managed without the need for surgery. The cortisol level is also important, since deficiency must be corrected especially in the perioperative period. Diagnosis of ACTH-secreting tumours can be difficult,

Figure 43.17 Pituitary non-functioning macroadenoma with suprasellar extension and right cavernous sinus invasion.

and may require the use of specialised tests, such as petrosal sinus sampling and the dexamethasone suppression test.

Effective treatment requires close cooperation between the neurosurgical team and an endocrinologist.

Prolactinomas are managed initially with dopamine agonists, such as bromocriptine and cabergoline. Growth hormone-secreting tumours may also respond to dopamine agonists, or to somatostatin analogues, such as octreotide.

Surgical resection is usually performed by a trans-sphenoidal approach, using a microscope or endoscope. Sometimes large tumours also require a craniotomy. After operation, patients are at risk of CSF leak (3 per cent) and pituitary insufficiency. Diabetes insipidus resulting from manipulation of the pituitary stalk is common in the immediate postoperative period and usually resolves spontaneously. Where it is suspected, the patient will require hourly measurement of urine output, and blood and urine samples for calculation of sodium concentration and osmolality. If confirmed, the condition can be managed with DDAVP (desmopressin) in consultation with endocrinology.

Urgent intervention is generally reserved for patients with deteriorating vision.

Pituitary apoplexy is the syndrome associated with haemorrhagic infarction of a pituitary tumour. It presents with sudden headache, visual loss and ophthalmoplegia with or without impaired conscious level. Intravenous steroids and urgent surgical decompression are required.

Vestibular schwannoma (acoustic neuroma)

These are nerve sheath tumours arising in the cerebellopontine angle, which present with hearing loss, tinnitus and balance problems. Facial numbness and weakness are less common, while large tumours may present with features of brainstem compression or hydrocephalus. The differential diagnosis includes meningioma, metastasis and epidermoid cyst (Figure 43.18).

Small intracanalicular tumours (within the internal auditory canal) may be managed with surveillance. For intermediate size tumours, radiosurgery is an alternative to operation. Large lesions (>4 cm), especially with brainstem compression, will require excision and consideration of ventriculoperitoneal shunt to relieve hydrocephalus. Translabyrinthine, retrosigmoid and middle fossa approaches are possible, the latter options offering potential preservation of hearing in smaller tumours with some intact function at presentation. In removing larger tumours, it is often impossible to preserve hearing, or indeed facial nerve function.

Brain tumours in children

Brain tumours are the most common solid tumours in children.

Neonates develop predominantly neuroectodermal tumours in supratentorial locations, including subtypes detailed below (see also Summary box 43.10):

- teratoma;
- primitive neuroectodermal tumour (PNET);
- high grade astrocytoma;
- choroid plexus papilloma/carcinoma.

Older children tend to suffer infratentorial tumours, especially:

- medulloblastoma (an infratentorial PNET);
- ependymoma;
- pilocytic astrocytoma.

Figure 43.18 The appearances of a meningioma in the left cerebellopontine angle (CPA), with a coexisting vestibular schwannoma in the right CPA.

Summary box 43.10

Other key tumour types

- Pituitary tumours typically present with endocrinological disturbance (microadenomas) or visual deficits due to compression (macroadenomas). Some of these tumours are managed surgically, in close cooperation with endocrinologists
- Vestibular schwannomas (acoustic neuromas) are benign nerve sheath tumours, usually presenting with hearing loss, tinnitus and balance problems. Their proximity to the brainstem allows them to cause significant morbidity and mortality, and can present a major surgical challenge
- A large variety of mostly neuroectodermal brain tumours represent the most common solid organ tumours in children

PAEDIATRIC NEUROSURGERY

Paediatric neurosurgery presents a wide range of isolated and syndrome-associated developmental abnormalities including cysts, neural tube defects and posterior fossa malformations. In general, these present with combinations of developmental delay, seizures, and macrocephaly or hydrocephalus. Early fusion of one or more cranial sutures, craniosynostosis, is also a common neonatal presentation.

Cysts

A number of benign fluid-filled intracranial lesions typically present incidentally, or with mass effect or hydrocephalus. Treatment of symptomatic or enlarging lesions is usually surgical, involving excision, endoscopic fenestration into a cistern or ventricle, or shunting for hydrocephalus.

Cyst types

- Arachnoid cyst – typically middle fossa, CSF enclosed in an envelope of arachnoid mater.
- Colloid cyst – occurs in the roof of the third ventricle, believed to represent embryonic endoderm remnants.
- Dermoid and epidermoid cysts – epithelial lined structures arising from displaced ectodermal remnants, typically in the posterior fossa (midline) and cerebellopontine angle, respectively.
- Porencephalic cysts – brain cavities lined with gliotic white matter, containing CSF in communication with the ventricles or subarachnoid space.

Neural tube defects

Failure of closure of the neural tube is associated with folate deficiency, family history and some anticonvulsants. Prenatal screening, using serum alphaprotein levels and ultrasound, and diagnostic testing, using amniocentesis, are possible. The spectrum of conditions associated with failed closure of the posterior neuropore includes:

- Spina bifida occulta: a congenital absence of a spinous process, without exposure of meninges or neural tissue, but presenting a characteristic shallow hair-covered hollow at the base of the spine. This is common and rarely clinically significant. Sometimes it may be associated with tethered cord syndrome,

which involves thickening of the filum terminale, resulting in traction on the cord. Presentation is with progressive deficits, spasticity, bladder dysfunction or scoliosis, and treatment involves surgical exploration and untethering of the cord.

- **Meningocele:** a sac of meninges, covered by skin and containing CSF alone, herniates through an anterior or posterior bony defect.
- **Myelomeningocele:** a herniating sac of meninges without covering skin contains spinal cord, nerves or both. This is always associated with Chiari II malformation (see below). Open myelomeningocele presents a high infection risk and requires early surgical repair.
- **Lipomyelomeningocele:** adipose tissue adherent to the spinal cord herniates through a bony defect to the sacrolumbar soft tissue. This may be associated with bladder dysfunction and requires surgical relief of the resultant cord tethering.

Failure of closure of the anterior neuropore produces anencephaly, which is uniformly fatal – the spectrum of spinal dysraphisms, however, is replicated in the skull. Cranium bifidum is a failure of fusion, often in the occipital region. This may be associated with herniation of meninges and CSF (meningocele), and potentially also brain substance (encephalocele) (Figure 43.19).

Figure 43.19 An occipital encephalocele.

Posterior fossa malformations

Chiari malformations involve cerebellar herniation through the foramen magnum:

- **Normal:** Up to 5 mm of cerebellar tonsillar descent through the foramen magnum
- **Chiari I:** >5 mm of tonsillar descent: presents typically in young adults with headache and variable neurological disturbance
- **Chiari II:** descent of the tonsils and vermis: presents in infancy with poor feeding, stridor and apnoeic episodes.

They are often associated with syringomyelia, the presence of a fluid-filled cavity (syrinx) in the spinal cord. Compression of the brainstem and cerebellum, or development of a syrinx, may cause neurological deficits. Shunting and foramen magnum decompression are the mainstay of treatment. Chiari malformations may also present incidentally or with headaches exacerbated by Valsalva.

Dandy Walker malformations present in infancy with macrocephaly, developmental delay and hydrocephalus; most patients

have associated abnormalities in the CNS and other organ systems. Imaging demonstrates a hypoplastic cerebellar vermis, with the posterior fossa occupied by a large thin-walled cyst. Treatment usually involves shunt placement.

Craniosynostosis

Normal fusion of the coronal, lambdoid, squamosal and sagittal sutures occurs between six and 12 months of age; others, such as the frontal suture fuse later. Craniosynostosis is the premature fusion of one (simple craniosynostosis) or more (complex craniosynostosis) cranial sutures, preventing growth perpendicular to the suture. This results in a range of skull deformities (see Table 43.6; Figures 43.20 and 43.21) and hydrocephalus. Syndromic craniosynostosis, often associated with abnormalities of the fibroblast growth factor receptor genes, is accompanied by developmental delay and other abnormalities. The surgical treatment aims to correct deformity and prevent development of raised ICP (Summary box 43.11).

Table 43.6 Types of craniosynostosis.

Type	Suture involved	Clinical features
Scaphocephaly	Sagittal suture	Narrow boat-shaped head
Brachycephaly	Coronal suture	Shortened/broad forehead
Microcephaly	All sutures involved	Small head
Plagiocephaly	Unilateral coronal/lambdoid suture	Asymmetric skull
Trigonocephaly	Metopic suture	Pointed narrow forehead

Summary box 43.11

Paediatric neurosurgery

Children manifest a range of developmental pathologies requiring neurosurgical management including:

- cysts
- neural tube defects
- posterior fossa abnormalities
- craniosynostosis

In general, intracranial pathologies present with features including developmental delay, seizures, macrocephaly and hydrocephalus.

FUNCTIONAL NEUROSURGERY

Where neurosurgery normally seeks to avoid disturbing neural tissue as far as possible, functional procedures aim to relieve epilepsy, movement disorders or pain by ablation or stimulation.

Epilepsy

Up to 10 per cent of the population will suffer a seizure at some point in their lives, and epilepsy, a syndrome of recurrent unprovoked seizures, represents the most common neurological

Figure 43.20 Characteristic appearance of scaphocephaly due to sagittal suture synostosis.

Figure 43.21 Axial computed tomography scan showing severe trigonocephaly due to premature fusion of the metopic suture.

disorder. About 20–30 per cent of patients fail to achieve adequate seizure control with drugs, and many of these focal epilepsies may benefit from surgery. Where a primary lesion, such as a tumour, arteriovenous malformation (AVM) or cavernoma is present, lesionectomy alone may be appropriate. In other cases, the clinical picture including seizure type, focal features and investigation results can be used to identify the seizure focus. Dual pathology refers to the presence of an extrahippocampal lesion plus hippocampal atrophy, important because removal of both the lesion and the atrophic hippocampus is the best surgical approach and should be considered whenever possible.

Investigation

MRI imaging is a mainstay, demonstrating for example reduced hippocampal volume and distorted architecture in mesial tem-

poral sclerosis. Nuclear medicine modalities including single-photon emission computed tomography (SPECT) and positron emission tomography (PET) are sometimes used to demonstrate ictal and inter-ictal metabolic abnormalities.

Electroencephalography (EEG) entails recording from an array of scalp electrodes, and comparison between ictal and inter-ictal recordings. This is especially helpful in lateralising the focus of complex partial seizures in temporal lobe epilepsy, and is combined with video monitoring of the seizure in a videotelemetry suite. A more detailed localisation may be achieved invasively by the preoperative placement of subdural or depth electrodes, preoperatively or by intraoperative electrocorticography (ECoG).

Neuropsychological evaluation is used to evaluate the patient's preoperative function looking for concordant focal impairments, and, using the Wada test where sodium amytal is injected into each internal carotid artery in turn, with simultaneous speech and memory testing to localise function. The aim is to establish language laterality and to confirm that resection on the side of the lesion will not significantly impair verbal memory function.

Surgical management

The seizure focus may be resected, generally where it is in non-eloquent brain, or otherwise a disconnection can be performed. Awake craniotomy, allowing mapping particularly of speech centres, is increasingly employed.

Mesial temporal epilepsy is commonly medically refractory and can be addressed surgically by amygdalohippocampectomy or resection of the temporal lobe including the mesial structures. The extent of resection is limited by the potential for damage to the optic tracts, and to speech areas in the dominant hemisphere. With careful patient selection, cure rates of up to 70 per cent or greater can be achieved.

Functional, or rarely anatomical, hemispherectomy (Figure 43.22) may be performed for specific epilepsy syndromes associated with hemiplegia, such as infantile hemiplegia syndrome. This is usually considered in the early years of life when plasticity and potential for functional recovery is greatest.

Disconnection procedures include corpus callosotomy, used for patients suffering drop attacks, and subpial transections to isolate a seizure focus in eloquent brain from the surrounding cortex.

Vagal nerves stimulators are implanted in severe drug refractory epilepsy, usually in children, and can achieve some success in reducing seizure frequency, although the mechanism is unclear, and is never curative.

Movement disorders

Prior to the advent of levodopa, surgical ablation of the subthalamic nucleus or globus pallidus interna was a mainstay of management for Parkinson's. Inhibition of the action of these centres remains a valuable tool later in the course of the disease as the therapeutic window using levodopa narrows, but this is now generally achieved using deep brain stimulation with electrodes. This offers the advantage of an adjustable and reversible effect, and can be performed bilaterally where equivalent lesioning surgery would likely result in deficits.

Figure 43.22 Coronal T2-weighted magnetic resonance imaging scan image following an anatomical hemispherectomy.

Deep brain stimulation is also an option for other movement disorders where less invasive approaches are ineffective. These include dystonias, which may be amenable to bilateral stimulation of the globus pallidus interna, and essential tremor where the ventral intermediate nucleus of the thalamus is the target.

Pain syndromes

Neurosurgical approaches to the relief of pain may address the underlying aetiology directly, or may seek to interrupt or modulate the transmission responsible for the pain. The contrasting approaches are demonstrated in the management of trigeminal neuralgia. This manifests, generally in middle age or later, with paroxysmal lancinating pain in the distribution of one or more divisions of the trigeminal nerve. The pain occurs without other neurological disturbance, and may be triggered by trivial stimuli such as eating or brushing the teeth. The pain was first attributed to stimulation of the nerve by an adjacent vascular structure, often the superior cerebellar artery, by Walter Dandy. Occasionally, another primary lesion is responsible; for example, bilateral trigeminal neuralgia in younger patients is suggestive of multiple sclerosis. Where medications, such as gabapentin and carbamazepine cannot achieve control, surgical options include:

- Craniotomy and microvascular decompression: this is designed to address the proposed origin of the neuropathic pain, by applying material between the nerve and adjacent vessel to prevent direct contact and stimulation. It achieves long-lasting relief of symptoms in about 80 per cent of patients,

Juhn Atsushi Wada, b.1924 Tokyo, appointed as Professor of Neurology, University of British Columbia, Vancouver, Canada in 1956. The test is also known as 'intracarotid sodium amobarbital' procedure.

James Parkinson, 1755–1824, a general practitioner of Shoreditch, London, UK.

but is associated with the standard risks of craniotomy (see below Risks of craniotomy, p. 19) and a significant incidence of cranial nerve deficit.

- Peripheral nerve injections, which can achieve good short-term relief of pain restricted to small areas supplied by terminal branches of the trigeminal.
- Percutaneous Gasserian rhizolysis: this involves needle placement under x-ray guidance at the Gasserian ganglion in Meckel's cave. This permits lesioning of the ganglion by glycerol injection, radiofrequency thermocoagulation or balloon compression, with the aim of disrupting aberrant pain transmission. A similar effect can also be achieved using stereotactic radiosurgery. Facial numbness and late recurrence of pain are common after these procedures.

Treatment of pain elsewhere may also be based on lesioning of nerve tracts. For example, pain related to brachial plexus infiltration or injury may be treated by sectioning the spinothalamic tract (cordotomy), or the dorsal root entry zone (DREZ operation). These approaches are limited by the potential for producing deficits, and especially by the occurrence of deafferentation ('phantom limb') pain syndromes which are particularly unpleasant and difficult to treat.

Electrical stimulation is used to modulate pain transmission; for example, spinal cord stimulators can be applied to a range of pain syndromes, especially those associated with failed spinal surgery. Deep brain stimulation targeting the periaqueductal grey and sensory thalamic nuclei has a role in chronic pain arising in the context of thalamic stroke.

Implanted devices may also be used for intrathecal delivery of opiates for pain control, or baclofen to alleviate spasticity (Summary box 43.12).

Summary box 43.12

Functional neurosurgery

- Intractable epilepsy can be treated surgically by implantation of a vagal nerve stimulator or by resection of one or more seizure foci
- Deep brain stimulation using implanted electrodes has largely replaced lesioning of these structures for management of drug-refractory Parkinson's disease
- Microvascular decompression is offered for trigeminal neuralgia, and other neuropathic pain syndromes may respond to lesioning of nerve tracts

OCCLUSIVE VASCULAR DISEASE

There is class 1 evidence for the role of carotid endarterectomy in reducing the risk of stroke in patients with symptomatic carotid stenosis, and a debatable role for the procedure in patients with no previous transient ischaemic episodes.

In a subgroup of otherwise fit patients with completed posterior fossa or non-dominant middle cerebral artery territory infarcts, there is a role for decompressive craniectomy in the acute setting to manage the brain swelling and raised ICP associated with the infarct.

Moya moya disease is the progressive obliteration of one or both internal carotid arteries, thought to represent an autoimmune process. The development of external carotid circulation

collaterals produces the angiographic 'puff of smoke' appearance responsible for this Japanese-derived name. It presents in youth or early middle age with ischaemia or haemorrhage. Untreated, the majority of patients suffer major deficit or die within two years. Ischaemia may be addressed by a variety of bypass techniques, for example by anastomosing the superficial temporal artery (arising from the external carotid) to the middle cerebral artery.

COMPRESSIVE NEUROPATHIES

Carpal tunnel syndrome is a compression neuropathy resulting from entrapment of the median nerve under the flexor retinaculum at the wrist. Risk factors include diabetes, obesity, thyroid disorders and acromegaly. The presentation is usually with paraesthesia in the hand, worse at night. Examination will reveal sensory disturbance in the median nerve distribution – the palmar aspect of the thumb, index and middle fingers, and the radial aspect of the ring finger. The palm itself is relatively spared, reflecting supply by the palmar cutaneous branch passing superficial to the retinaculum. Wasting of the thenar eminence, and weakness of abductor pollicis brevis may also be apparent, and tapping over the carpal tunnel (Tinel's test) or wrist flexion (Phalen's test) may reproduce symptoms. Nerve conduction studies confirm the diagnosis, and management includes wrist splints, steroid injections, and carpal tunnel decompression by division and release of the flexor retinaculum.

A range of related peripheral mononeuropathies, characterised by sensory disturbance, wasting and weakness in the nerve distribution, are investigated using nerve conduction studies, and are typically amenable to surgical decompression. Common examples include:

- Ulnar nerve entrapment at the elbow: the sensory disturbance affects the little finger and ulnar aspect of the ring finger, and wasting of the hypothenar eminence may be evident. Froment's sign is elicited by asking the patient to hold a piece of paper in the first webspace while the examiner attempts to slide it away; the distal phalanx of the thumb is seen to flex, reflecting the use of flexor pollicis longus (anterior interosseous innervated) instead of adductor pollicis (ulnar innervated, so weak).
- Meralgia paraesthetica: the lateral cutaneous nerve of the thigh is compressed under the inguinal ligament, producing sensory disturbance in the lateral thigh.

PRACTICAL AND ETHICAL ISSUES

Creutzfeldt-Jakob disease

CJD is a rare transmissible spongiform encephalopathy producing a rapidly progressive dementia, and is uniformly fatal. The causative agent seems to be a mis-folded protein, a prion, which is not destroyed by conventional sterilisation techniques. UK practice involves undertaking preoperative checks to exclude any risk factors for CJD infection. These include family history,

George S Phalen, contemporary, orthopaedic surgeon and Chief of Hand Surgery, The Cleveland Clinic, Cleveland, OH, USA. He helped to establish the American Society for Surgery of the Hand.

receipt of pituitary-derived human growth hormone, cadaveric dura mater grafts, and previous brain or spinal surgery prior to 1997. Where risk factors are present, instruments must be quarantined or destroyed postoperatively.

Risks of craniotomy

The risks associated with craniotomy are important to appreciate in discussing operations with patients and family, and in evaluating patients who deteriorate postoperatively. The figures quoted in brackets will vary significantly between individual procedures and even between centres:

- infection (5 per cent) and wound breakdown;
- intracerebral haemorrhage;
- seizures;
- CSF leak;
- permanent neurological deficit;
- death (1 per cent).

Brainstem death

This is defined as the irreversible loss of cerebral and brainstem function. Brainstem death is legally equivalent to death, and is a pre-condition for the harvesting of organs for transplant from heart-beating donors.

Diagnosis requires:

- identification of the cause of irreversible coma;
- exclusion of reversible causes of coma;
- clinical demonstration of the absence of brainstem function.

In the UK, this entails testing twice, by two clinicians, to demonstrate the absence of:

- response to pain;
- respiratory drive (apnoea despite a $p\text{CO}_2 > 6.7$ kPa);
- pupillary light reflex;
- corneal reflex;
- vestibulo-ocular reflex;
- oculoccephalic reflex;
- gag reflex.

LEARNING OBJECTIVES

To understand and appreciate:

- The common ocular disorders and recognise ophthalmic symptoms and specific signs
- The value of special investigations
- When specialist referral is appropriate

OCULAR ANATOMY

Adnexae

The lids comprise skin, connective tissue, the orbicularis oculi (VIIth cranial nerve) and the tarsal plate, with multiple meibomian glands opening posterior to the lashes and lined with conjunctiva, which is reflected onto the sclera. The upper lid is elevated by the levator muscle (IIIrd cranial nerve) and has a horizontal strip of sympathetically innervated Müller's muscle, giving rise to 2 mm of ptosis in Horner's syndrome. Both lids are attached to the orbital rim by the medial and lateral canthal tendons. Both have a rich vascular supply and are innervated by the V1 division of the trigeminal nerve (Vth cranial nerve) above and the V2 division below.

Lacrimal system

The almond-shaped lacrimal gland lies under the upper outer orbital rim and opens into the upper conjunctival fornix through 10–15 ducts. Tears are swept across the globe by the lids and evaporate or pass into the upper and lower lid puncta, and then into the canaliculi to join the common canaliculus, which passes into the lacrimal sac under the medial canthal tendon. The sac is drained by the nasolacrimal duct into the nose, opening in the inferior meatus under the inferior turbinate.

The globe

The cornea is the 12-mm diameter window of the eye, 0.5 mm thick centrally; its clarity is due to the regular arrangement of collagen bundles and relative dehydration. It merges into the sclera at the corneoscleral junction (the limbus), the insertion of the bulbar conjunctiva. The sclera, which is 1 mm thick, comprises four-fifths of the wall of the eye, and gives attachment to the extraocular muscles. It is perforated by the long and short posterior ciliary arteries and the vortex veins and is contiguous with the optic nerve sheath. The uvea comprises iris, ciliary body and vascular choroid. The optic nerve is continuous with the retina and retinal pigment epithelium. The most sensitive part of the retina, the macula, lies at the posterior pole within the vascular arcade. The biconvex lens and capsule

are suspended by the suspensory ligament, over 300 tiny fibres attached to the ciliary muscle. Aqueous humour arises from the ciliary processes, hydrates the vitreous gel, passes through the pupil into the anterior chamber between the iris and the cornea and then drains out through the trabecular meshwork into Schlemm's canal in the drainage angle. The inner retina is supplied by the central retinal artery and drained by the central retinal vein (Figure 44.1).

Orbit

The orbit is four-sided and pyramidal in structure, housing the globe, optic nerve, the four rectus and two oblique muscles, the lacrimal gland, orbital fat, the IIIrd, IVth, Vth and VIth cranial

Figure 44.1 Anatomy of the eye.

nerves, the ophthalmic artery with its tributaries and the ophthalmic veins, which anastomose anteriorly with the face and posteriorly with the cranial cavity. Above is the frontal lobe of the brain, temporally the temporal fossa, inferiorly the maxillary sinus and nasally the lacrimal sac and ethmoidal and sphenoidal air sinuses. The optic nerve passes through the optic canal to the chiasm, with other nerves and vessels passing through the superior orbital fissure.

PERIORBITAL AND ORBITAL SWELLINGS

Swellings related to the supraorbital margin

Dermoid cysts

Dermoid cysts are usually external angular cysts although they may occur medially (Figure 44.2). They often cause a bony depression by their pressure and they may have a dumbbell extension into the orbit. They can also erode the orbital plate of the frontal bone to become attached to dura and for this reason it is important to image the area by computed tomography (CT) before excision.

Neurofibromatosis

Neurofibromatosis may also produce swellings above the eye. The diagnosis can usually be confirmed by an examination of the whole body, as there are often multiple lesions. Proptosis can also result (Figure 44.3). Other ophthalmic features may be present.

Swellings of the lids

Meibomian cysts (chalazion)

These are the most common lid swellings (Figure 44.4). A meibomian cyst is a chronic granulomatous inflammation of a meibomian gland. It may occur on either upper or lower lids and presents as a smooth, painless swelling. It can be felt by rolling the cyst on the tarsal plate. It can be distinguished from a sty (hordeolum), which is an infection of a hair follicle and is usually painful. Persistent meibomian cysts are treated by incision and curettage from the conjunctival surface. Styes are treated by antibiotics and local heat.

Figure 44.2 External angular dermoid.

Figure 44.3 Neurofibroma in the orbit with proptosis, and also similar lesions in the forehead.

Figure 44.4 Meibomian cyst (courtesy of Mr D Spalton, FRCS).

Basal cell carcinomas (rodent ulcers)

This is the most common malignant tumour of the eyelids (Figure 44.5). It is locally malignant, is more common on the lower lids and usually starts as a small pimple that ulcerates and has raised edges ('rodent ulcer'). It is easily excised in the early stages. Histological confirmation that the excision is complete is required. More extensive lesions may require specialist techniques, such as Mohs' micrographic surgical excision controlled by frozen section. Local radiotherapy or cryotherapy can be carried out; however, recurrence is more common, more aggressive and more difficult to detect (Summary box 44.1).

Frederic E Mohs, 1910–2002, physician and general surgeon, University of Wisconsin, Madison, WI, USA. Developed Mohs' micrographic surgical technique in 1938 for cutaneous malignant lesions.

Figure 44.5 Rodent ulcers (courtesy of Mr J Beare, FRCS).

Summary box 44.1

Basal cell carcinomas

- Basal cell carcinomas are the most common malignant eye tumour
- Treatment is by excision with care with histopathological margin control
- All unusual lesions (especially in the elderly) should be biopsied

Other lid swellings

Other types of lid swelling can occur but they are less common. They include sebaceous cysts, papillomas, keratoacanthomas, cysts of Moll (sweat glands) (Figure 44.6) or Zeis (sebaceous glands) and molluscum contagiosum. When molluscum contagiosum occurs on the lid margin, it can give rise to a mild viral chronic keratoconjunctivitis and should be curetted or excised.

Carcinoma of the meibomian glands and rhabdomyosarcomas are rare lesions; they need to be treated by radical excision. Atypical or meibomian cysts that recur should be biopsied.

Figure 44.6 Cyst of Moll.

Swellings of the lacrimal system

Lacrimal sac mucocele

This occurs from obstruction of the lacrimal duct beyond the sac and results in a fluctuant swelling that bulges out just below the medial canthus. It can become infected to give rise to a painful tense swelling (acute dacryocystitis). If untreated it may give rise to a fistula. Treatment is by performing a bypass operation between the lacrimal sac and the nose (a dacryocystorhinostomy (DCR)). Watering of the eye can occur due to eversion of the lower lid (ectropion), which causes loss of contact between the lower punctum and the tear film, or from reflex hypersecretion as a result of irritation of inturning lashes in entropion, and these must be distinguished from a mucocele.

Lacrimal gland tumours

These are swellings of the lacrimal glands, which lie in the upper lateral aspect of the orbit. Eventually, they lead to impairment of ocular movements and displacement of the globe forwards, downwards and inwards. Pathologically the tumours resemble parotid tumours and they can be pleomorphic adenomas with or without malignant change, carcinomas or mucoepidermoid tumours.

Orbital swellings

Orbital swellings result in displacement of the globe and limitation of movement. A full description of orbital swellings is outside the realm of this text but some of the most common causes include the following:

- **Pseudoproptosis.** This results from a large eyeball, as seen in congenital glaucoma or high myopia.
- **Orbital inflammatory conditions** that result in orbital cellulitis (Figure 44.7).
- **Haemorrhage** after trauma or retrobulbar injection.
- **Neoplasia** affecting the lacrimal gland, the optic nerve, the orbital walls or the nasal sinuses, e.g. glioma (neurofibromatosis) (see Figure 44.3), meningioma and osteoma (Figure 44.8).
- **Dysthyroid exophthalmos** (Figures 44.9, 44.10 and 44.11). This may be unrelated to active thyroid disease but can start after thyroidectomy and may need urgent tarsorrhaphy, large doses of steroids or even orbital lateral wall decompression if the eyeball is threatened by exposure or optic nerve compression. CT and magnetic resonance imaging (MRI) scans are useful in diagnosis.

Figure 44.7 Orbital cellulitis.

Figure 44.10 Magnetic resonance imaging scan of a coronal view of the orbit, showing enlarged muscles in thyroid disease (courtesy of Dr Juliette Britton).

Figure 44.11 Exophthalmos in dysthyroid eye disease.

- **Pseudotumour**, or malignant lymphoma.
- **Haemangiomas** of the orbit (Figure 44.12).
- **Tumour metastases**. These are rare. In children they usually arise from neuroblastomas of the adrenal gland, whereas in adults the oesophagus, stomach, breast and prostate can be sites of primary lesions.

Diagnostic aids

Diagnostic aids include radiography, CT, MRI, ultrasonography and, less commonly, tomography and orbital venography.

Treatment

Treatment is directed to the cause of the lesion if at all possible, taking care to prevent exposure of the eye, diplopia or visual impairment from optic nerve compression.

INTRAOCULAR TUMOURS

Children

Retinoblastoma is a multicentric malignant tumour of the retina, which can be bilateral. Some are sporadic, but many are hereditary. Children with a family history should be carefully monitored from birth. It is often not spotted until the tumour fills the globe and presents as a white reflex in the pupil or as a squint (Figure 44.13). The differential diagnosis includes retinopathy of prematurity, primary hyperplastic vitreous and intraocular infections. If the tumour is large, enucleation may be required, but radiotherapy, cryotherapy, chemotherapy or laser treatment can cure small lesions. Liaison with a paediatric oncologist is essential (Summary box 44.2).

Figure 44.12 Capillary haemangioma in a child. An orbital venogram demonstrates displacement of the second part of the superior ophthalmic vein (arrow) (courtesy of Dr Glyn Lloyd).

Figure 44.13 Retinoblastoma giving rise to a white pupillary reflex (courtesy of MA Bedford, FRCS).

Summary box 44.2

Intraocular tumours

- All children with a squint should have a fundal examination to exclude a retinoblastoma
- A blind painful eye may hide a melanoma

Adults

Malignant melanoma is the most common tumour and it originates in the pigment cells of the choroid (Figure 44.14), ciliary body or iris. It can present with a reduction in vision, a vitreous haemorrhage or by the chance finding of an elevated pigmented lesion in the eye. Tumour growth is variable but, as a general rule, the more posterior the lesion, the more rapidly progressive it is likely to be. Spread may be delayed for many years; however, the liver is frequently involved, hence the advice 'beware of the patient with a glass eye and an enlarged liver'. Treatment

Figure 44.14 Choroidal melanoma.

is by light or laser coagulation, radioactive plaque, radiotherapy, enucleation and, in selected cases, local excision using hypotensive anaesthesia. Diagnosis is made by direct observation and/or ultrasound, which shows a solid tumour (Figure 44.15).

INJURIES INVOLVING THE EYE AND ADJACENT STRUCTURES

Corneal abrasions and ulceration

The cornea is frequently damaged by direct trauma or by foreign bodies (Figure 44.16). Ulceration can occur with infection or after damage to the facial nerve. Post-herpetic ulceration is common and serious if not treated. Fluorescein instillation illuminated by blue light shows up corneal ulceration at an early stage (Summary box 44.3).

Summary box 44.3

Corneal abrasions

- A drop of fluorescein dye illuminated by a blue light reveals even the smallest corneal abrasion

Treatment is by protection (eye pads, tarsorrhaphy or a bandage contact lens) and antibiotics topically and rarely systemically: 0.5 per cent chloramphenicol or ofloxacin eye

Figure 44.15 B-scan showing choroidal melanoma (courtesy of Dr Marie Reston).

Figure 44.16 Corneal foreign body.

drops are commonly used. The eye is made more comfortable by the use of mydriatics, such as homatropine or cyclopentolate. Herpes simplex dendritic ulcers are treated with aciclovir ointment. In countries in the Far and Middle East, chronic infection with trachoma can cause corneal opacification and blindness. Corneal grafting is the only cure for an opaque cornea. Until recently, full thickness penetrating keratoplasty was the only corneal graft technique. This has largely been replaced by lamellar or partial thickness graft surgery, in a technique termed DSEK or 'Descamets stripping endothelial keratoplasty'. Rarely, osteo-odonto keratoprosthesis can be attempted in very severe cases of opaque corneas that are not suitable for grafting. Acanthamoeba is a rare serious cause of corneal infection. This infection usually follows the use of contact lenses. Specialist management and treatment is recommended.

Blunt injuries to the eye and orbit

The floor of the orbit is its weakest wall and in blunt trauma, such as a blow from a fist, it is often fractured without fractures of the other walls. This is called a blow-out fracture. Clinical signs are enophthalmos, bruising around the orbit, maxillary hypoesthesia, limitation of upward gaze due to entrapment of the inferior rectus muscle leading to vertical diplopia. This occurs when the extraocular muscles or orbital septa become trapped in the fracture and can be identified as a soft-tissue mass in the antrum on a radiograph (Figure 44.17), although CT scans or tomograms may be necessary. Surgical repair of the orbital floor with freeing of the trapped contents may be necessary if troublesome diplopia persists or enophthalmos is marked. A child with an orbital floor fracture requires urgent assessment as a 'greenstick' fracture can result in ischaemia of a trapped inferior rectus muscle and may require urgent surgery. If an orbital haemorrhage is too extensive to examine the eye, it may be necessary to examine the eye under anaesthesia because there may be a hidden perforation of the globe. Injuries to the lids and lid margins must be repaired, and if the lacrimal canaliculi are damaged they should be repaired if possible, especially the lower canaliculus as 75 per cent of tear drainage goes through it.

Blunt injuries can also cause damage to the optic nerve, which can result in blindness and a total afferent pupillary defect (Figures 44.18 and 44.19).

Figure 44.17 Radiograph showing a blow-out fracture of the orbit (left) with soft tissue in the antrum (courtesy of Dr Glyn Lloyd).

Concussion injuries

Concussion injuries of the eye can give rise to several problems, which include the following:

- **Iritis.** Inflammation, treated with topical steroids.
- **Hyphaema** (blood in the anterior chamber) (Figure 44.20). Rest and sedation, particularly in children, are advised because the main danger in this condition is secondary bleeding, resulting in an acute rise in intraocular pressure and blood staining of the cornea. The use of antifibrinolytic agents (ϵ -aminocaproic acid) has been advocated and, if the pressure rises, surgery to wash out the blood may be necessary.

Figure 44.18 Injury from a ski stick into the right brow. Vision reduced to 'no perception of light' (courtesy of J Beare, FRCS).

Figure 44.19 Scan of orbit from Figure 44.18 showing a massive swelling of the medial rectus (courtesy of J Beare, FRCS).

Figure 44.20 Hyphaema. Blood in the vitreous chamber after concussion injury.

Figure 44.21 Retinal haemorrhage from a cricket bat injury (courtesy of J Beare, FRCS).

- **Subluxation of the lens.** This is suspected if the iris, or part of the iris, 'wobbles' on movement (iridodonesis).
- **Secondary glaucoma.** This is often associated with recession of the drainage angle.
- **Retinal and macular haemorrhages and choroidal tears** (Figure 44.21).
- **Retinal dialysis.** This may lead to a retinal detachment and permanent damage to vision (Figure 44.22).

Penetrating eye injuries

These occur when the globe is penetrated, often in road traffic and other major accidents (Figure 44.23), and also in injuries from sharp instruments. The compulsory wearing of seatbelts in motor vehicles has substantially reduced the incidence of this type of eye injury, by up to 73 per cent in the UK. The presence of an irregular pupil suggests prolapse of the iris and should arouse the suspicion of a penetrating injury. Treatment is prompt primary repair to restore the integrity of the globe. If a perforation is suspected, extensive eye examination should not

Figure 44.22 Retinal dialysis after concussional injury.

Figure 44.23 Facial lacerations from a windscreen injury. Beware of a perforating eye injury.

be attempted before anaesthesia because this may lead to further extrusion of the intraocular contents. If the fundal view is poor, ultrasonography and orbital imaging are indicated. Secondary corneal grafting, lensectomy and vitrectomy have considerably improved the visual prognosis; these must be done by an experienced eye surgeon. Injuries to the optic nerves must also be excluded in severe accidents.

Intraocular foreign bodies

Intraocular foreign bodies must always be excluded when patients attend the accident and emergency department with an eye injury and a history of working with a hammer and chisel or a history of a potentially high-velocity injury. Radiography of the orbits should always be performed, and ferrous and copper foreign bodies should always be removed, sometimes requiring the use of a magnet. B-scan ultrasonography can also assist in localising foreign bodies when a vitreous haemorrhage or cataract is present. CT can be used, but MRI is contraindicated (Summary box 44.4).

Summary box 44.4

Penetrating eye injuries

- A distorted and irregular pupil warrants the careful exclusion of a penetrating eye injury

Burns

Radiation burns

These occur following exposure to ultraviolet radiation after arc welding or excessive sunlight (snow blindness) and sun lamps. Such burns cause intense gritty burning pain and photophobia as a result of keratitis (corneal inflammation), which starts some hours after exposure. Mydriatic and local steroids with antibiotic drops ease the condition, and healing usually occurs after 24 hours.

Thermal burns

If these involve the full thickness of the lids, corneal scarring may occur from exposure, and immediate corneal protection is necessary. A splash of molten metal may cause marked local necrosis and may lead to permanent corneal scarring. Treatment

Figure 44.24 Chemical burn showing conjunctival necrosis.

is to remove any debris by irrigation and to instill local atropine, antibiotics and steroids to prevent superadded infection and scarring. Lid reconstruction may be necessary.

Chemical burns

Chemical burns, and especially alkali burns, can be serious because ocular penetration occurs quickly and ischaemic necrosis can result (Figure 44.24). Immediate copious irrigation until the pH is neutral will ensure that the chemical is diluted as much as possible, and all particles should be removed from the fornices. Treatment can then be continued as with thermal burns. Well-fitting goggles should prevent such injuries.

DIFFERENTIAL DIAGNOSIS OF THE ACUTE RED EYE

This is important in the management of minor ocular complaints and the recognition of conditions that require expert attention. Possible causes of the acute red eye include:

- subconjunctival haemorrhage
- conjunctivitis
- keratitis
- uveitis
- episcleritis and scleritis
- acute glaucoma.

Any condition with pain, visual impairment or a pupil abnormality suggests a more serious diagnosis.

Subconjunctival haemorrhage

This presents as a bright-red eye, often noticed incidentally, with only minimal discomfort and normal vision. Causes include coughing, sneezing, minor trauma, hypertension and, rarely, a bleeding disorder. Reassurance and treatment of the underlying cause are required. Most settle within a week, but can recur.

Conjunctivitis

Symptoms are grittiness, redness and discharge. Causes are infective, chemical, allergic or traumatic. In the newborn, it can be serious; gonococcal and chlamydial infection must be excluded. Bacterial conjunctivitis is purulent, usually self-limiting and treated with topical broad-spectrum antibiotics. Chlamydial and

Figure 44.25 Vernal conjunctivitis (spring catarrh) showing cobblestone appearance under the upper lid.

adenovirus infections must be considered. Adenoviral infections are common and usually affect one eye much more in severity and onset, tending to be more watery than sticky, and are often associated with a palpable preauricular gland.

Vernal conjunctivitis (Figure 44.25) is a form of allergic conjunctivitis, characterised by itchy eyes, usually worse in the spring and early summer and often associated with other allergic problems such as hay fever. Clinically, most signs are under the upper lid, which may have a cobblestone appearance instead of a smooth surface.

Giant pupillary conjunctivitis with large papillae under the upper lid may be seen in soft contact lens wearers. This is usually caused by an allergy to the sterilising solutions and lens protein and may be helped by either using a preservative-free solution or using daily-wear disposable lenses.

Kaposi's sarcoma can rarely present like a subconjunctival haemorrhage (Figure 44.26).

Considerable conjunctival and corneal irritation can be caused by the lids turning in (entropion) (Figure 44.27) or turning out (ectropion) (Figures 44.28 and 44.29), and by ingrowing lashes. The lids should be repaired surgically to their normal position.

Figure 44.26 Kaposi's sarcoma of conjunctiva.

Figure 44.27 Entropion (courtesy of J Beare, FRCS).

Vision is not commonly affected in conjunctivitis but, with some viral infections, a keratitis may be present and result in visual impairment and pain. All of the other conditions described below are painful and usually affect vision.

Keratitis (inflammation of the cornea)

Herpes simplex infection presents as a dendritic (branching) ulcer, shown easily by staining with fluorescein or Bengal Rose. It is treated with aciclovir ointment five times per day. The use of steroid drops must be avoided as this can make the condition much worse (Figure 44.30).

Corneal ulceration may occur as a result of ingrowing lashes or corneal foreign bodies, marginal ulceration and infected abrasions. Infected ulcers can occur in patients wearing soft contact

Figure 44.30 Dendritic staining caused by herpes keratitis.

lenses or elderly immunocompromised individuals. Herpes zoster (shingles) may affect the ophthalmic division of the Vth nerve and can give rise to a keratitis and uveitis. It is important to avoid the use of steroid drops until a diagnosis has been made. Local anaesthetic drops should also not be given on a regular basis.

Uveitis

This can be anterior (iritis) or, more rarely, posterior. In anterior uveitis, the pupil will be small, sometimes irregular, there is circumcorneal injection and there may be keratic precipitates present on the posterior surface of the cornea. Pain, photophobia and some visual loss are usually present. Posterior uveitis can present with a white eye and blurred vision. It usually takes a chronic course. Granulomatous diseases, Behçet's disease, Reiter's syndrome, toxoplasmosis and cytomegalovirus infection should be excluded. Topical systemic steroids and, sometimes, immunosuppressive drugs are useful in treating these conditions.

Episcleritis and scleritis

Episcleritis or inflammation of the episcleral tissue often occurs as an idiopathic condition (Figure 44.31).

Scleritis is a less common, more serious, condition in which the deeper sclera is involved. There is often an associated uveitis

Figure 44.28 Ectropion, lower lid (courtesy of J Beare, FRCS).

Figure 44.29 Ectropion, upper lid – chronic staphylococcal infection (courtesy of J Beare, FRCS).

Figure 44.31 Episcleritis.

Bengal Rose (or Rose Bengal) is dichlorotetraiodofluorescein.

Hulusi Behçet, 1889–1948, Professor of Dermatology, Istanbul, Turkey, described this disease in 1937.

Hans Conrad Julius Reiter, 1881–1968, President of the Health Service, and Honorary Professor of Hygiene at the University of Berlin, Germany, described this disease in 1916.

and severe pain. Thinning of the sclera may result. Systemic non-steroidal anti-inflammatory drugs (NSAIDs) or steroids may be required to treat the condition adequately.

Scleritis is often associated with severe rheumatoid conditions. The presence of scleritis suggests that there is active systemic disease and it requires systemic work-up including renal function tests.

Acute glaucoma

This usually occurs in older, often hypermetropic, patients. The cornea becomes hazy, the pupil oval, dilated and non-reacting, the vision poor and the eye feels hard. In severe cases, pain may be accompanied by vomiting and the condition can be mistaken for an acute abdominal problem. Tonometry (intraocular pressure measurement) is diagnostic. Urgent treatment to reduce the pressure with pilocarpine, acetazolamide and, if refractory, mannitol should be started, followed by YAG laser iridotomy or surgical iridectomy. The condition is usually bilateral and the second eye usually needs a prophylactic iridotomy at the same time.

Except for a simple conjunctivitis and subconjunctival haemorrhage, which are self-limiting, the management of an acute red eye requires expert treatment and a specialist opinion should be sought. A painful eye with a IIIrd nerve palsy (ptosis, dilated pupil, globe down and out) often signifies an intracranial aneurysm and should be investigated immediately.

PAINLESS LOSS OF VISION

This may occur in one or both eyes, and the visual loss may be transient or permanent. Possible causes are:

- Acute:
 - obstruction of the central retinal artery (Figure 44.32);
 - obstruction of the central retinal vein (Figure 44.33);
 - ischaemic optic neuropathy;
 - migraine and other vascular causes;
 - vitreous and retinal haemorrhages;
 - retinal detachment (Figure 44.34);
 - macular hole, cyst or haemorrhage;
 - cystoid macular oedema, often after surgery;
 - hysterical blindness.
- Chronic:
 - cataract;
 - glaucoma;
 - macular degeneration;
 - diabetic retinopathy;

Specialist help should be sought in any case of loss of vision. The erythrocyte sedimentation rate and C-reactive protein should be measured immediately if cranial arteritis is suspected, and the carotid system should be examined for bruits and other signs of arteriosclerosis in cases of ischaemic optic neuropathy and central retinal artery occlusion. Glaucoma, hypertension, hyperviscosity syndromes and diabetes should be looked for in cases of central vein thrombosis.

RECENT DEVELOPMENTS IN EYE SURGERY

In the last three decades, eye surgery has become a microsurgical specialty. Cataract surgery has been transformed by changes in local anaesthesia, implants, phacoemulsification and small-

Figure 44.32 Retinal artery occlusion.

Figure 44.33 Central retinal vein occlusion.

Figure 44.34 B-scan of a retinal detachment.

incision surgery, which allow compressible/foldable silicone or acrylic implants to be inserted through a 2-mm incision. The implant power can be more accurately measured by new formulae and the use of A-scan ultrasonography or laser wavefront

biometry, and multifocal and accommodative lenses are now available.

There are new treatments for eye disorders that involve abnormal growth of blood vessels in the back of the eye, such as the wet form of age-related macular degeneration. Monoclonal anti-vascular endothelial growth factor (VEGF) antibodies, such as the drug ranibizumab, may be injected directly into the vitreous cavity to reduce new vessel proliferation. Intravitreal steroid injections help to treat cystoid macular oedema.

Developments in vitreous surgery have enabled membranes to be peeled off the retina and macular holes to be repaired. They have also increased the success rate in retinal detachment surgery with the additional use of gases and silicone oil or heavy liquid inserted into the vitreous cavity tamponading the retina.

Some paralytic squints can be helped by the use of adjustable sutures or injections of botulinum toxin into the overacting muscles.

Refractive errors can be treated by the excimer laser. These can be combined with laser *in situ* keratomileusis (LASIK) surgery, which involves cutting a corneal flap (by femtosecond laser or surgery) and performing the laser surgery at a deeper level. There have been some concerns about defective contrast sensitivity and problems with night vision after laser correction of myopia. Phakic implants have also been used to correct high refractive errors. Corneal topography aids the accuracy of corneal and refractive surgery and the increased use and quality of CT and MRI scans has revolutionised the diagnosis of orbital and intracranial lesions involving the optic pathways (Figures 44.35, 44.36 and 44.37).

Fluorescein angiography, and ocular coherence tomography (OCT) are invaluable in the diagnosis and treatment of macular conditions. The glaucoma detection (GDx) retinal nerve fibre analyser and Heidelberg retinal tomography (HRT) are increasingly used in the diagnosis and management of glaucoma.

LASERS IN OPHTHALMOLOGY

Argon blue-green or diode laser is used to treat the retina in diabetic retinopathy (pan-retinal photocoagulation from proliferative disease or focal treatment for leaky microaneurysms),

Figure 44.35 Magnetic resonance imaging scan, sagittal view. Craniopharyngioma. The mass in the suprasellar cistern is of high signal intensity because of the proteinaceous fluid that the cyst contains (courtesy of Dr Juliette Britton).

Figure 44.36 High-resolution computed tomography through the orbits showing dense calcification of the optic nerve sheaths typical of optic nerve meningioma (courtesy of Dr Juliette Britton).

Figure 44.37 Axial enhanced magnetic resonance imaging scan showing a mass involving the optic chiasma and extending down the optic nerves and tracts.

and is also used to close retinal tears or breaks that might lead to retinal detachment.

Argon laser or selective laser trabeculoplasty can be used to open the drainage angle to control elevated intraocular pressure in open angle glaucoma. Trans-scleral diode photocoagulation of the ciliary body is used to treat refractory secondary glaucoma with uncontrolled ocular pressure.

Laser iridotomy with the Nd:YAG laser is used to treat both the affected and fellow eye in acute angle closure glaucoma. The Nd:YAG laser is also used to photodisrupt and clean an opaque posterior capsule which occurs in 5–10 per cent of cases following cataract surgery.

SURGICAL PROCEDURES

Excision of an eyeball/enucleation

Indications include a blind, painful eye, a blind, cosmetically poor eye/intraocular neoplasm and, in cadavers, for use in corneal grafting.

The operation

The speculum is introduced between the lids and opened. The conjunctiva is picked up with toothed forceps and divided completely all round as near as possible to the cornea. Tenon's capsule is entered and each of the four rectus and two oblique muscle tendons is hooked up on a strabismus hook and divided close to the sclera. The speculum is now pressed backwards and the eyeball projects forwards. Blunt scissors, curved on the flat, are insinuated on the inner side of the globe, and these are used to sever the optic nerve. The eyeball can now be drawn forwards with the forceps, and the oblique muscles, together with any other strands of tissue that are still attaching the globe to the orbit, are divided. A swab, moistened with hot water and pressed into the orbit, will control the haemorrhage. If an orbital implant is inserted to give better eye movement, the muscles are sutured to the implant at the appropriate sites. The subconjunctival tissues and conjunctiva are closed in layers.

Evisceration of an eyeball

Evisceration is preferred to excision in endophthalmitis, minimising the risk of orbital and intracranial spread with meningitis. The sclera is transfixated with a pointed knife a little behind the corneosclerotic junction, and the cornea is removed entirely by completing the encircling incision in the sclera. The contents of the globe are then removed with a curette, care being exercised to remove all of the uveal tract. At the end of the operation the interior must appear perfectly white. A ball orbital implant made of acrylic or hydroxyapatite is placed within the orbit behind the sclera to improve the appearance when the artificial eye is fitted.

Incision and curettage of chalazion (meibomian cyst)

The lid margin is everted to allow the application of a meibomian clamp. The ring of the clamp is placed on the palpebral conjunctiva with the granuloma in the centre. An incision is made with a small blade in the axis of the gland. The herniating granulomatous tissue is removed with a curette and the cavity is scraped clean. Recurrent cysts may have to have the cyst wall dissected away with scissors. A biopsy may be necessary in atypical or recurrent cysts to exclude malignant change.

CHAPTER
45Cleft lip and palate:
developmental abnormalities of
the face, mouth and jaws

LEARNING OBJECTIVES

To understand:

- The aetiology and classification of cleft lip and palate
- The principles of reconstruction of cleft lip and palate
- The key features of the perioperative care of the child with cleft lip and palate
- The associated complications of cleft lip and palate and their management

INTRODUCTION

Clefts of the lip, alveolus and hard and soft palate are the most common congenital abnormalities of the orofacial structures. They frequently occur as isolated deformities, but can be associated with other medical conditions, particularly congenital heart disease. They are also an associated feature in over 300 recognised syndromes.

All children born with a cleft lip and palate need a thorough paediatric assessment to exclude other congenital abnormalities. In certain circumstances, genetic counselling must be sought if a syndrome is suspected.

INCIDENCE

The incidence of cleft lip and palate is 1:600 live births and of isolated cleft palate is 1:1000 live births. The incidence increases in Oriental groups (1:500) and decreases in the black population (1:2000). The highest incidence reported for cleft lip and palate occurs in the Indian tribes of Montana, USA (1:276).

Although cleft lip and palate is an extremely diverse and variable congenital abnormality, several distinct subgroups exist, namely cleft lip with/without cleft palate (CL/P), cleft palate (CP) alone and submucous cleft palate (SMCP).

The typical distribution of cleft types is:

- cleft lip alone: 15 per cent;
- cleft lip and palate: 45 per cent;
- isolated cleft palate: 40 per cent.

Cleft lip/palate predominates in males, whereas cleft palate alone appears to be more common in females. In unilateral cleft lip, the deformity affects the left side in 60 per cent of cases.

AETIOLOGY

Contemporary opinion on the aetiology of cleft lip and palate is that cleft lip and palate and isolated cleft palate have a genetic predisposition and a contributory environmental component. A family history of cleft lip and palate in which the first-degree relative is affected increases the risk to 1:25 live births. Genetic influence is more significant in cleft lip/palate than cleft palate alone, in which environmental factors exert a greater influence.

Environmental factors implicated in clefting include maternal epilepsy and drugs, e.g. steroids, diazepam and phenytoin. The role of antenatal folic acid supplements in preventing cleft lip and palate remains equivocal.

Although most clefts of the lip and palate occur as an isolated deformity, Pierre Robin sequence remains the most common syndrome. This syndrome comprises isolated cleft palate, retrognathia and a posteriorly displaced tongue (glossoptosis), which is associated with early respiratory and feeding difficulties.

Isolated cleft palate is more commonly associated with a syndrome than cleft lip/palate and cleft lip alone. Over 150 syndromes are associated with cleft lip and palate, although Stickler's (ophthalmic and musculoskeletal abnormalities), Shprintzen's (cardiac anomalies), Down's, Apert's and Treacher Collins' syndromes are most frequently encountered (Summary box 45.1).

Summary box 45.1**Cleft lip and palate**

- Associated with other congenital abnormalities
- Incidence varies between races from 1:300 to 1:2000 live births
- Aetiology is both genetic and environmental

Pierre Robin, 1867–1950, professor, The French School of Dentistry, Paris, France, described this syndrome in 1929.

Gunnar B Stickler, 1925–2010, born in Germany, Chair of Section of Paediatrics and later Paediatric Cardiology, The Mayo Clinic, Rochester, MN, USA.

Robert J Shprintzen, born 1946, surgeon, Syracuse, NY, USA.

John Langdon Haydon Down (sometimes given as Langdon-Brown), 1828–1896, physician, The London Hospital, UK, published the classification of aments in 1866.

Eugene Apert, 1868–1940, physician, L'Hopital des Enfants-Malades, Paris, France, described this syndrome in 1906.

Edward Treacher Collins, 1862–1932, ophthalmic surgeon, the Royal London Ophthalmic Hospital, and Charing Cross Hospital, London, UK, described this syndrome in 1900.

ANATOMY OF CLEFT LIP AND PALATE

Cleft lip

The abnormalities in cleft lip are the direct consequence of disruption of the muscles of the upper lip and nasolabial region. The facial muscles (Figure 45.1) can be divided into three muscular rings of Delaire: the nasolabial muscle ring surrounds the nasal aperture; the bilabial muscle ring surrounds the oral aperture; and the labiomental muscle ring envelops the lower lip and chin regions.

Unilateral cleft lip

In the unilateral cleft lip, the nasolabial and bilabial muscle rings are disrupted on one side resulting in an asymmetrical deformity involving the external nasal cartilages, nasal septum and anterior maxilla (premaxilla) (Figure 45.2a and b). These deformities influence the mucocutaneous tissues causing a displacement of nasal skin onto the lip and a retraction of labial skin, as well as changes to the vermilion and lip mucosa. All these changes need to be considered in planning the surgical repair of the unilateral cleft lip.

Bilateral cleft lip

In the bilateral cleft lip, the deformity is more profound but symmetrical. The two superior muscular rings are disrupted on both sides producing a flaring of the nose (caused by lack of nasolabial muscle continuity), a protrusive premaxilla and an area of skin in front of the premaxilla devoid of muscle, known as the prolabium (Figure 45.3a and b). As in the unilateral cleft lip, the muscular, cartilaginous and skeletal deformities influence the mucocutaneous tissues, which must be respected in planning the repair of the bilateral cleft lip.

Cleft palate

Embryologically, the **primary** palate consists of all anatomical structures anterior to the incisive foramen, namely the alveolus

and upper lip. The **secondary** palate is defined as the remainder of the palate behind the incisive foramen, divided into the hard palate and, more posteriorly, the soft palate.

Cleft palate results in failure of fusion of the two palatine shelves. This failure may be confined to the soft palate alone or involve both hard and soft palate. When the cleft of the hard palate remains attached to the nasal septum and vomer, the cleft is termed **incomplete**. When the nasal septum and vomer are completely separated from the palatine processes, the cleft palate is termed **complete** (Summary box 45.2).

Summary box 45.2

Types of cleft palate

- May involve the soft palate or the soft and hard palate
- It is complete when nasal septum and vomer are separated from the palatine process

Figure 45.1 The muscle chains of the face: frontal view. The nasal cartilages are represented in blue. A, nasolabial (muscles 1–3); B, bilabial (muscles 4–6); C, labiomental (muscles 7–9); 1, transverse nasalis; 2, levator labii superioris alaeque nasi; 3, levator labii superioris; 4, orbicularis oris (oblique head) – upper lip; 5, orbicularis oris (horizontal head) – upper lip; 6, orbicularis oris – lower lip; 7, depressor anguli oris; 8, depressor labii inferioris; 9, mentalis.

Figure 45.2 (a) Schematic representation of disruption of the nasolabial and bilabial muscle chains in unilateral (left) cleft lip. A, nasolabial; B, bilabial; C, labiomental. (b) Unilateral cleft lip before muscular reconstruction.

Figure 45.3 (a) Schematic representation of disruption of the nasolabial and bilabial muscle chains in bilateral cleft lip. A, nasolabial; B, bilabial; C, labiomental. (b) Bilateral cleft lip before muscular reconstruction.

Soft palate

In the normal soft palate, closure of the velopharynx, which is essential for normal speech, is achieved by five different muscles functioning in a complete but coordinated fashion. In general, the muscle fibres of the soft palate are orientated transversely with no significant attachment to the hard palate.

In a cleft of the soft palate (Figure 45.4a) the muscle fibres are orientated in an anteroposterior direction, inserting into the posterior edge of the hard palate (Figure 45.4b).

Hard palate

The normal hard palate can be divided into three anatomical and physiological zones (Figure 45.5). The central **palatal fibromucosa** is very thin and lies directly below the floor of nose. The **maxillary fibromucosa** is thick and contains the greater palatine neurovascular bundle. The **gingival fibromucosa** lies more lateral and adjacent to the teeth.

Figure 45.4 (a) Cleft of soft palate and incomplete cleft of hard palate. (b) Muscles of the soft palate: left, cleft palate; right, normal anatomy. A, tensor palati; B, levator palati; C, palatopharyngeus; D, palatoglossus; E, musculus uvulae.

Figure 45.5 The three mucosal zones of the hard palate. 1, palatal fibromucosa; 2, maxillary fibromucosa; 3, gingival fibromucosa.

In performing surgical closure of cleft palate the changes associated with the cleft must be understood to obtain an anatomical and functional repair. In complete cleft palate, the median part of the palatal vault is absent and the palatal fibromucosa is reduced in size. The maxillary and gingival fibromucosa are not modified in thickness, width or position.

CLASSIFICATION

Any classification for such a diverse and varied condition as cleft lip and palate needs to be simple, concise, flexible and exact but graphic. It must be suitable for computerisation but descriptive and morphological. An example of such a classification is the LAHSHAL system, which is able to describe site, size and extent, as well as type of cleft (Figure 45.6).

Complete clefts of the lip, alveolus and hard and soft palate are designated as capitals L, A, H and S, respectively. Incomplete clefts are recorded in lower case letters whereas microform clefts are documented with asterisks. Hence, LAHSHAL is the anatomical paraphrase of a complete bilateral cleft lip and palate. Another example, lahSh, represents an incomplete right unilateral cleft lip and alveolus with a complete cleft of soft palate extending partly onto the hard palate.

Figure 45.6 LAHSHAL: an anatomical representation of cleft lip (L), alveolus (A) and hard (H) and soft palate (S).

PRIMARY MANAGEMENT

Antenatal diagnosis

An antenatal diagnosis of cleft lip, whether unilateral or bilateral, is possible by ultrasound scan after 18 weeks of gestation. Isolated cleft palate cannot be diagnosed by antenatal scan. When an antenatal diagnosis is confirmed, referral to a cleft surgeon is appropriate for counselling to allay fears. Photographs of cleft lip shown to parents 'before and after' surgery are invaluable. Introduction to a parent support group and meeting parents of a child with a similar cleft who has undergone surgery may also be extremely helpful (Summary box 45.3).

Summary box 45.3

Antenatal diagnosis and counselling

- All but isolated cleft palate can be diagnosed by ultrasound scan after 18 weeks' gestation
- Parents will need counselling and support

Feeding

Most babies born with cleft lip and palate feed well and thrive, provided that appropriate advice is given and support is available. Some mothers are successful in breastfeeding, particularly when the cleft is incomplete and confined to the lip. Good feeding patterns can be established with soft bottles (e.g. Mead Johnson) and modified teats (orthodontic, Nuyk). Simple measures, such as enlarging the hole in the teat, often suffice. Feeding plates, constructed from a dental impression of the upper jaw, are rarely necessary to improve feeding. Some babies are provided with an active plate that aims not only to improve feeding but also reduce the width of the cleft lip and palate prior to surgery. The long-term benefit of such a regime remains unproven.

Airway

Major respiratory obstruction is uncommon and occurs exclusively in babies with Pierre Robin sequence. Hypoxic episodes during sleep and feeding can be life-threatening. Intermittent airway obstruction is more frequent and is managed by nursing the baby prone. More severe and persistent airway compromise can be managed by 'retained nasopharyngeal intubation' to maintain the airway. Surgical adhesion of the tongue to the lower lip (labioglossopexy) in the first few days after birth is an alternative but less commonly practised method of management (Summary box 45.4).

Summary box 45.4

Problems immediately after birth

- Some babies are able to feed normally but some will need assistance
- Breathing problems in Pierre Robin sequence may be life-threatening

PRINCIPLES OF CLEFT SURGERY

The ultimate goal in cleft lip and palate management is a patient with a normal appearance of lip, nose and face, whose speech is normal and whose dentition and facial growth fall within the range of normal development.

Surgical techniques are aimed at restoring normal anatomy. With the exception of rare conditions such as holoprosencephaly, there is no true hypoplasia of the tissues involved on either side of the cleft. There is, however, displacement, deformation and underdevelopment of the muscles and facial skeleton. Emphasis is placed on muscular reconstruction of the lip, nose and face, as well as muscles of the soft palate. Normal

or near-normal anatomy promotes normal function, thereby encouraging normal growth and development of lip, nose, palate and facial skeleton. An in-depth understanding of the anatomy of the cleft is invaluable if the surgeon is to achieve normal, or near-normal, anatomical reconstruction (Summary box 45.5).

Summary box 45.5

Surgical anatomy

- Normal lip, face and nose
- There is underdevelopment and displacement of the muscles
- Restoration of normal anatomy encourages normal facial growth and function

Surgical techniques

There have been many different surgical techniques and sequences advocated in cleft lip and palate management. Cleft lip repair is commonly performed between three and six months of age, whereas cleft palate repair is frequently performed between six and 18 months.

The Delaire technique and sequence (Table 45.1) is one of many regimes currently practised.

Cleft lip surgery

Skin incisions (Figures 45.7 and 45.8) are developed to restore displaced tissues, including skin and cartilage, to their normal position, while gaining access to the facial, nasal and lip musculature.

Table 45.1 Timing of primary cleft lip and palate procedures (after Delaire).

Cleft lip alone		
Unilateral (one side)	One operation	at 5–6 months
Bilateral (both sides)	One operation	at 4–5 months
Cleft palate alone		
Soft palate only	One operation	at 6 months
Soft and hard palate	Two operations	Soft palate at 6 months Hard palate at 15–18 months
Cleft lip and palate		
Unilateral	Two operations	Cleft lip and soft palate at 5–6 months Hard palate and gum pad with or without lip revision at 15–18 months
Bilateral	Two operations	Cleft lip and soft palate at 4–5 months Hard palate and gum pad with or without lip revision at 15–18 months

Figure 45.7 (a and b) Skin incisions (highlighted in red) for left unilateral complete cleft lip (after Delaire).

Figure 45.8 (a–c) Skin incisions for bilateral complete cleft lip, showing the shaded area from Figure 45.7a. Areas for removal of excess mucosa (a) or skin (b) (after Delaire).

Muscular continuity is achieved by subperiosteal undermining over the anterior maxilla. Nasolabial muscles are anchored to the premaxilla with non-resorbable sutures. Oblique muscles of orbicularis oris are sutured to the base of the anterior nasal spine and cartilaginous nasal septum. Closure of the cleft lip is completed by suturing the horizontal fibres of orbicularis oris to achieve a functioning oral sphincter (Figures 45.9 and 45.10).

When the cleft lip is incomplete (Figures 45.11a and 45.12a), meticulous assessment of the cleft deformity is of paramount importance, as complete muscle disruption may be present leading to nasal and skeletal deformity. Full muscular exposure and reconstruction is imperative in many incomplete clefts if facial symmetry is to be achieved (Figures 45.11b and 45.12b).

Cleft palate surgery

Cleft palate closure can be achieved by one- or two-stage palatoplasty. The surgical principle is mobilisation and reconstruction of the aberrant soft palate musculature (Figure 45.13a and b), together with closure of the residual hard palate cleft by minimal dissection and subsequent scar formation (Figure 45.14a and b). Excess scar formation in the palate adversely affects growth and development of the maxilla. The philosophy of two-stage closure encourages a physiological narrowing of the hard palate cleft to minimise surgical dissection at the time of the second procedure (Summary box 45.6).

Summary box 45.6

Principles of surgery

- Cleft lip surgery attaches and reconnects the muscles around the oral sphincter
- Cleft palate surgery aims to bring together mucosa and muscles with minimal scarring
- Two-stage procedures attempt to minimise dissection

Figure 45.9 Unilateral complete cleft lip before (a) and after (b) muscular reconstruction.

SECONDARY MANAGEMENT

Following primary surgery, regular review by a multidisciplinary team is essential. Many aspects of cleft care require long-term review:

- hearing
- speech
- dental development
- facial growth.

Figure 45.10 Bilateral cleft lip before (a) and after (b) muscular reconstruction.

Hearing

Eustachian tube dysfunction plays a central role in the pathogenesis of otitis media with effusion in babies and children born with a cleft palate. Children with a cleft lip alone exhibit

Figure 45.11 Unilateral incomplete cleft lip before (a) and after (b) muscle reconstruction.

the same frequency of otitis media as their age-matched non-cleft counterparts. It has been recently recognised that a child with a craniofacial anomaly including cleft lip and palate is at increased risk of a sensorineural hearing deficit. All children born with a cleft lip and palate should undergo assessment before 12 months of age for **sensorineural and conductive hearing loss** by auditory brainstem responses (ABR) and tympanometry, respectively.

Sensorineural hearing loss is managed with a hearing aid whereas the management of secretory otitis media remains more controversial. Early (6–12 months) prophylactic myringotomy and grommet insertion temporarily eliminates middle ear effusion. Regular audiological testing may be as appropriate, reserving surgery for established secretory otitis media with infection. No firm evidence is available to support the interventional approach over the conservative regime. Nevertheless, the relationship between hearing loss and potential speech problems remains important. Regular audiological assessment during childhood is of utmost importance.

Speech

Initial speech assessment should be performed early (18 months) and repeated regularly to ensure that problems are identified early and managed appropriately.

Common speech problems associated with cleft lip and palate are:

- **Velopharyngeal incompetence.** This is associated with increased nasal airflow and resonance, producing a nasal

or 'hypernasal' quality to speech. It frequently reflects poor function of the soft palate associated with inadequate muscle repair.

- **Articulation problems.** These arise either as a compensatory mechanism to overcome velopharyngeal incompetence or, less commonly, are caused by jaw/dental and occlusal abnormalities. Videofluoroscopy, nasal airflow studies (aerophonoscopy) and nasendoscopy are helpful in defining the exact mechanism of the problem, aiding management.
- **Speech problems.** These are managed by speech and language therapy; secondary palatal surgery, either intravelar veloplasty (muscular reconstruction of soft palate) or pharyngoplasty; and speech training devices (Summary box 45.7).

Summary box 45.7

Associated hearing and speech problems

- Higher incidence of sensorineural and conductive hearing loss
- Regular hearing tests are important if speech is to develop normally
- Speech problems may result from airflow problems

Dental

Dental anomalies are common findings in children with cleft lip and/or palate. Various phenomena including delayed tooth development, delayed eruption of teeth and morphological

Figure 45.12 Bilateral incomplete cleft lip before (a) and after (b) muscular reconstruction.

Figure 45.13 (a and b) Method of repair of cleft palate. First-stage palatoplasty to reconstruct muscles of the soft palate. Red lines represent incisions, and orange areas raw surfaces.

Figure 45.14 (a and b) Schematic representation of closure of the hard palate. Second-stage palatoplasty achieved with two-layered closure. Red lines represent incisions, and orange areas raw surfaces.

abnormalities are well documented. The number of teeth may be reduced (hypodontia) or increased (hyperdontia), occurring most commonly in the region of the cleft alveolus involving the maxillary lateral incisor tooth. These abnormalities can occur in both primary and secondary dentition.

All children with cleft lip and palate should undergo regular dental examination. Dental management should also include preventative measures, such as dietary advice, fluoride supplements and fissure sealants.

A well-maintained and disease-free dentition in childhood is an absolute prerequisite for orthodontic treatment (Summary box 45.8).

Summary box 45.8

Dental problems

- Too many/too few teeth or problems with eruption of teeth are common
- Good dentition is essential for successful reconstructive surgery

Orthodontic management

Many children with cleft lip and palate require orthodontic treatment. Orthodontic treatment is commonly carried out in two phases:

- 1 Mixed dentition (8–10 years) – to expand the maxillary arches as a prelude to alveolar bone graft.
- 2 Permanent dentition (14–18 years) – to align the dentition and provide a normal functioning occlusion. This phase of treatment may also include surgical correction of a malpositioned/retrusive maxilla by maxillary osteotomy (Figure 45.15a and b).

Secondary surgery for cleft lip and palate

Good outcome in cleft lip and palate is directly attributable to the quality of the primary surgery. Secondary cleft procedures include:

- cleft lip revision (unilateral and bilateral);
- alveolar bone graft;
- simultaneous lip revision and alveolar bone graft;
- secondary palate procedures, e.g. veloplasty and pharyngoplasty, closure of a palatal fistula;
- dentoalveolar procedures, including transplantation of teeth/insertion of osseointegrated dental implants;
- orthognathic surgery;
- rhinoplasty.

Cleft lip revision

Indications for revisional surgery to the previously repaired cleft lip are dependent on the site and severity of the residual deformity.

Revisional surgery should be delayed for two years after primary lip closure unless the surgeon is of the opinion that the initial procedure was inadequate, particularly with respect to muscular reconstruction.

Indications for revision include:

- lip deformity:
 - malaligned vermillion;
 - asymmetrical Cupid's bow;
 - muscle discontinuity or malalignment;
- nasal deformity:
 - lateral drift of alar base;
 - poor nasal tip projection;
 - deviation of cartilaginous nasal septum into the non-cleft nostril.

Residual nasal deformity is an external manifestation of incomplete reconstruction of the nasolabial muscle ring.

Examples of lip revision are shown in Figures 45.16, 45.17, 45.18 and 45.19 (Summary box 45.9).

Summary box 45.9

Cleft lip revision surgery

- Should be delayed for at least two years after primary surgery
- Aims to improve incomplete primary reconstruction

Figure 45.15 Correction of midface retrusion by maxillary advancement osteotomy, before (a) and after (b) surgery.

Alveolar bone grafting

Alveolar bone grafting in a mixed dentition is a well-established procedure for patients with a residual alveolar cleft associated with cleft lip and palate. The rationale for performing alveolar bone grafting includes:

Figure 45.16 (a) Revision of unilateral complete cleft lip, seen from below. (b) Skin incisions. (c) Wide exposure of nasolabial and orbicularis oris muscle. (d) Lip closure highlighting improved nasal symmetry.

- stabilisation of maxillary segments;
- to promote eruption of the canine tooth into the cleft site;
- to enhance bony support of the teeth adjacent to the cleft alveolus;
- to promote closure of the oronasal fistula;
- to close residual fistula of the anterior palate;

- to provide adequate bone stock to receive an osseointegrated dental implant where a tooth is congenitally absent.

Normally, but not universally, patients undergo a period of orthodontic treatment prior to bone grafting. The collapsed maxillary segment is expanded orthodontically to widen the

Figure 45.17 (a) Asymmetrical Cupid's bow. Revision of unilateral cleft lip – skin markings. (b) Identification and realignment of orbicularis oris muscle. (c) Postoperative appearance.

cleft alveolus. The surgery is best performed before the canine tooth erupts (between 8 and 11 years of age). There is a consensus that earlier bone grafting may be beneficial not only for the unerupted canine tooth but also to promote eruption and bony support to the adjacent central and lateral incisor when present. Alveolar bone grafting can also be performed simultaneously with secondary lip revision (Figure 45.20).

Cancellous bone is harvested from either the iliac crest or tibial plateau. This is achieved either through an open approach or preferably through a small incision utilising a trephine. When

Figure 45.18 (a) Revision of bilateral cleft lip with reconstruction of nasolabial muscles. (b) Skin incisions and development of philtrum. (c) Postoperative view – improved nasal and lip symmetry.

the defect is very small, alternative bone sites, e.g. mental symphysis, are sometimes advocated. Bone grafting is a highly successful procedure when carried out in experienced hands, with over 90 per cent of patients achieving acceptable interdental alveolar bone height, but it does require the interaction of surgeon and orthodontist. When the lateral incisor is absent and the canine tooth fails to erupt, surgical exposure of the canine

Figure 45.19 (a) Revision of left unilateral cleft lip to correct nasal deformity. (b) Skin incision. (c) Postoperative view.

Figure 45.20 (a) Intraoperative view of alveolar bone graft demonstrating defect in alveolus (arrow) (simultaneous lip revision). (b) Cancellous bone graft (arrow) packed into defect.

tooth may be required to aid its eruption. It is a fundamental principle that, following alveolar bone grafting, efforts should be made to ensure that a tooth erupts into the alveolar bone graft site. Failure to provide a tooth in the alveolar bone graft site usually results in bony resorption in the long term. This can be overcome by the insertion of an osseointegrated implant into the grafted site, thereby preserving bone stock (Figure 45.21) (Summary box 45.10).

Summary box 45.10

Alveolar bone grafting

- Aimed at stabilising orthodontic treatment
- Promotes normal eruption of canine and other teeth

Orthognathic surgery

Impaired growth of the midface (maxilla) is now attributed to poor and traumatic primary surgery. Surgical techniques must endeavour to minimise scarring, although in many cases patients have a genetic predisposition to poor midfacial growth. Elective maxillary advancement or bimaxillary surgery is often indicated to restore aesthetics and dental occlusal harmony. Orthognathic

Figure 45.21 Radiographic appearance of an implant in an alveolar bone graft site.

surgery is usually performed when facial growth is complete (16 years in female patients, 19 years in male patients).

The principal dentofacial deformity associated with cleft lip and palate is underdevelopment in both the horizontal and vertical direction of the maxilla. This leads to a pseudoprognathism in late adolescence, which is not correctable by orthodontic fixed-appliance therapy alone. Patients needing orthognathic surgery can be identified as early as ten years old, although planning and treatment does not commence until 14–15 years of age. Treatment with fixed appliances to align teeth in each dental arch is carried out over a period of 18–24 months as a prelude to orthognathic surgery. Orthognathic surgery may require maxillary osteotomy advancement alone (Figure 45.15a and b) or bimaxillary osteotomy and genioplasty (Figure 45.22). Rigid fixation, with or without bone grafting of the maxilla, is essential as cleft lip and palate patients undergoing orthognathic surgery have a high risk of a skeletal relapse as a result of the scarring associated with primary cleft lip and palate surgery.

Open septorhinoplasty

Following revisional cleft lip and palate surgery, orthognathic surgery and alveolar bone grafting, many patients still require definitive surgical nasal correction. In patients with cleft lip and palate, open rhinoplasty is preferred to gain access to the external cartilaginous framework, which is frequently deformed (Figure 45.23). The principal deformity is a collapse of the lower lateral cartilage on the cleft side, together with a dislocation of the cartilaginous septum into the non-cleft nostril. The open method ensures adequate access and repositioning of the cartilaginous framework as a tertiary procedure to improve nasal tip projection, correct septal deformity and relocate alar cartilages. A postauricular onlay graft to the middle crus of the cleft nostril lower lateral cartilage may be required to enhance good nasal tip projection and symmetry (Summary box 45.11).

Summary box 45.11

Deformities requiring nasal reconstruction

- Collapse of the lower lateral cartilage on the cleft side
- Dislocation of cartilaginous septum into the non-cleft nostril

Figure 45.22 (a) Lateral view of an adult with previously repaired cleft lip and palate demonstrating mandibular prognathism and maxillary retrusion. (b) Postoperative appearance following maxillary advancement and mandibular setback surgery.

Summary

The management of children with cleft lip and palate is complex, requiring the skill of a multidisciplinary team. Each team should include professionals who are appropriately qualified with specialist training, treating an adequate number of patients per year in centralised units. Meticulous record keeping of

Figure 45.23 (a) Characteristic nasal deformity of a non-functional unilateral cleft lip repair. (b) Incisions for open rhinoplasty. (c) Exposure of the cartilaginous skeleton of the external nose. (d) Repositioning of external nasal cartilages to improve nasal tip projection.

photography, radiology, dental casts and speech recordings are indispensable to permit regular audits and improve outcomes.

DEVELOPMENTAL ABNORMALITIES OF THE TEETH AND JAWS

Teeth

Developmental abnormalities of the teeth can be divided into:

- abnormality in number;
- defects of structure and size;
- disorders of eruption of teeth.

Number

Anodontia is the term that is strictly applied to congenital absence of all teeth, which may involve both deciduous and permanent dentition. This is a rare condition that is often hereditary.

Partial anodontia is a much more common disorder in which there is a failure of development of the primary or, more commonly, the secondary dentition. Teeth that are most frequently absent are the third molars (wisdom teeth), second premolars and maxillary lateral incisor teeth.

Partial anodontia is associated with certain congenital disorders:

- ectodermal dysplasia;
- Down's syndrome;
- cleft lip and palate.

Management of partial anodontia involves prosthetic replacement of the teeth, usually in combination with orthodontic treatment. Congenitally missing teeth can be replaced with removable prostheses, fixed prostheses or, more recently, the use of osseointegrated dental implants.

Additional teeth (**hyperdontia**) can occur alone or in association with other syndromes. Additional teeth are termed **supernumerary** teeth and are often impacted in the jaw with abnormal morphology. The most common site for supernumerary teeth is the maxillary incisor region, particularly in the midline (mesiodens). When additional teeth are of a similar morphology to the normal dentition, the term supplemental is appropriate. Supplemental teeth are common in the maxillary incisor and premolar regions, and less common in the wisdom tooth region when they are termed the fourth molars. Most supernumerary teeth are removed to encourage the eruption of the permanent dentition (Summary box 45.12).

Summary box 45.12

Problems with numbers of teeth

- Absent teeth can be replaced with prosthetic teeth, which may involve osseointegrated implants
- Supernumerary teeth are often impacted and are removed to allow eruption of secondary dentition

Defects of the structure of teeth

Structural changes of the teeth can occur as a consequence of genetic disorders or environmental factors.

Genetic disorders frequently include **amelogenesis imperfecta** and **dentinogenesis imperfecta**, which affect the enamel and dentine of the teeth, respectively. Both of these conditions are characterised by defects in both dentitions, in which all teeth are affected. In amelogenesis imperfecta, the defects are variable and may involve changes in structure (hypoplasia) or in mineralisation (hypocalcification). The loss of enamel leads to rapid attrition of the teeth to gum level in early adolescence. Dentinogenesis imperfecta results in soft dentine associated with short roots. Dentinogenesis imperfecta is strongly associated with osteogenesis imperfecta.

Acquired conditions producing changes in the structure of the teeth may be either local or systemic. Local causes are usually the consequence of trauma to the deciduous predecessor tooth, which interferes with enamel formation (amelogenesis). Common examples of systemic causes that produce tooth structure disruption are:

- measles
- rickets
- hypoparathyroidism
- tetracycline
- fluoride (Summary box 45.13).

Summary box 45.13

Causes of defects of the structure of teeth

Congenital

- Amelogenesis imperfecta
- Dentinogenesis imperfecta

Acquired local

- Trauma

Acquired systemic

- Disease – measles, rickets
- Drugs – fluoride, tetracycline

Disorders of eruption

Both primary and secondary dentition erupt in a specific sequence, although the timing of eruption does vary from child to child. Delayed eruption of teeth may involve a single tooth or may involve the entire dentition.

Local factors

There are numerous factors that impair the eruption of a single tooth. These include:

- loss of space/overcrowding
- additional teeth
- dentigerous cysts
- retention of deciduous tooth.

Systemic factors

These can prevent the eruption of multiple teeth. Examples of such conditions include:

- metabolic diseases – cretinism and rickets
- osteodystrophies – cleidocranial dysostosis and fibrous dysplasia
- hereditary gingival fibromatosis.

Management of unerupted teeth involves the removal of the obstruction to eruption, including supernumerary teeth, as well

as the relief of crowding. Patients with cleidocranial dysostosis should undergo long-term follow up with regular radiographic assessment. Supernumerary teeth, as and when they appear, should be removed to encourage the eruption of permanent dentition in adolescence. Many patients with cleidocranial dysostosis require multiple operations to expose teeth and encourage eruption (Summary box 45.14).

Summary box 45.14

Management of unerupted teeth

- Remove obstruction to eruption
- Surgical exposure if eruption delayed

Jaws

Disproportionate growth between the maxilla and mandible can occur, which results in derangement of the dental occlusion. The occlusion can be classified into three different subtypes:

- class I: a normal relationship of upper and lower incisors and molar dentition;
- class II: the mandibular teeth are placed posterior to the maxillary teeth;

- class III: the mandibular teeth are placed anterior to the maxillary teeth.

This classification is usually, but not invariably, the consequence of aberrant skeletal development of the maxilla and mandible, such that in a class II condition there is usually an underdevelopment of the mandible (mandibular retrognathia), whereas in a class III condition there may be simultaneous overgrowth of the mandible (mandibular prognathism) and underdevelopment of the maxilla (maxillary hypoplasia).

In the Caucasian population, the most common deformity of the facial skeleton is an underdevelopment of the mandible (retrognathia), producing a skeletal class II relationship often associated with excessive vertical growth of the maxilla. Bimaxillary protrusion is rare but is a characteristic of African races.

Condylar hyperplasia is an idiopathic condition seen in patients between 15 and 30 years of age, more common in women than men, in which there is hyperplasia or overgrowth of the neck of the mandibular condyle. This gives an asymmetrical growth to the jaw in both a vertical and horizontal plane.

Facial disproportionate growth is also a characteristic of many syndromes. Examples include:

- Treacher Collins' syndrome
- Crouzon's syndrome
- Apert's syndrome
- Pierre Robin sequence.

Figure 45.26 (a) Condylar hyperplasia with mandibular asymmetry. (b) Bone scan revealing increased bone activity in the right mandibular condyle. (c) Postoperative appearance following bimaxillary osteotomy to correct facial asymmetry.

Orthognathic surgery

Orthognathic surgery is the term given to the surgical correction of deformities of the jaw. It is usually undertaken in close cooperation between orthodontic and maxillofacial surgeons. Surgery is directed at simultaneously changing the position of both maxilla and mandible at the end of the growth period. This is termed bimaxillary osteotomy. Treatment planning usually commences at the age of 12–13 years, in which the orthodontist aligns the dental arches in correct relation for each jaw. This frequently results in an accentuation of the facial deformity at the end of the orthodontic phase of treatment. Treatment normally takes two years, in which orthognathic surgery is performed towards the end of orthodontic treatment, although orthodontic treatment in the form of fixed appliances usually continues postoperatively for up to six months after surgery. Surgical planning should be meticulous and involves clinical examination and cephalometric assessment in the form of radiograph analysis, as well as study model analysis, working in close cooperation with maxillofacial technologists.

Orthognathic surgery is generally carried out through intraoral incisions, in which the upper and lower jaws are mobilised by achieving osteotomy cuts with saws and drills (Figure 45.24). Following mobilisation of the mandible and maxilla, the jaws are repositioned and held with titanium plates and screws placed through an intraoral approach. This frequently avoids the use of intermaxillary fixation and allows earlier function of the jaws, as well as improved early dietary intake. Examples of orthognathic surgery are shown in Figures 45.25 and 45.26.

Patients with syndromic conditions, such as hemifacial microsomia and Crouzon's and Treacher Collins' syndromes, require the services of a craniofacial surgeon. As these syndromes are extremely rare, management and surgery should only be carried

out in designated centres. The principal treatment is to correct the deformity from the cranium downwards, with correction of the cranial deformity within the first three years of life and correction of the residual midfacial and lower facial deformity in childhood and adolescence.

The use of distraction osteogenesis in the management of craniofacial deformity has reduced the requirements for major orthognathic surgery in patients with severe facial deformity (Summary box 45.15).

Summary box 45.15

Principles of orthognathic surgery

- Orthodontist aligns the dental arches
- Surgery then corrects the jaw deformity

CHAPTER 46

The nose and sinuses

LEARNING OBJECTIVES

To be familiar with:

- The basic anatomy of the nose and paranasal sinuses
- The principles of managing post-traumatic nasal and septal deformity
- The causes and management of epistaxis
- The diagnosis and management of nasal polyposis
- The clinical features of sinus infection and its treatment and potential complications
- The common sinonasal tumours, their presentation, investigation and principles of treatment

BASIC ANATOMY OF THE NOSE AND PARANASAL SINUSES

The supporting structures of the nose are shown in Figure 46.1. The septum consists of the anterior quadrilateral cartilage, the perpendicular plate of the ethmoid and the vomer (Figure 46.2). The lateral wall of the nasal cavity contains the superior, middle and inferior turbinates (Figure 46.3). Opening onto the lateral

Figure 46.1 The nasal skeleton.

Figure 46.2 The left side of the nasal septum.

Figure 46.3 The right lateral nasal wall.

nasal wall are the ostia of all of the nasal sinuses, except the sphenoid sinus (Figures 46.4 and 46.5).

The nasal fossae and sinuses receive their blood supply via the external and internal carotid arteries. The external carotid artery supplies the interior of the nose via the maxillary and sphenopalatine arteries. The greater palatine artery supplies the

Figure 46.4 The right lateral nasal wall with turbinates removed to show the sinus ostia. A, insertion of superior turbinate; B, insertion of middle turbinate; C, insertion of inferior turbinate; SM, superior meatus; MM, middle meatus; IM, inferior meatus.

Figure 46.5 Coronal section through the left maxillary and ethmoid sinuses.

anteroinferior septum via the incisive canal. The contribution from the internal carotid artery is via the anterior and posterior ethmoidal arteries, which are branches of the ophthalmic artery (Figure 46.6). All of these arteries anastomose to form a plexus of vessels (Kiesselbach's plexus) on the anterior part of the nasal septum. Venous drainage is via the ophthalmic and facial veins and the pterygoid and pharyngeal plexuses. Intracranial drainage into the cavernous sinus via the ophthalmic vein is of particular clinical importance because of the potential for intracranial spread of nasal sepsis.

EXAMINATION OF THE NOSE AND PARANASAL SINUSES

Internal inspection of the nasal fossae can be achieved to a limited extent with the use of a Thudichum's speculum. A more thorough examination and assessment of the nose is possible with the use of either rigid or flexible endoscopes.

IMAGING OF PARANASAL SINUSES

Plain radiographs are of limited value in the assessment of sinus disease. A minimum of four views, namely occipitontal, occipitofrontal, submentovertical and lateral, are required to demonstrate the paranasal sinuses adequately. Computed tomography (CT) scanning is far superior in demonstrating sinus pathology. Coronal and axial scans are necessary for detailed assessment.

Figure 46.6 Arterial blood supply to the left side of the nasal septum.

TRAUMA TO THE NOSE AND PARANASAL SINUSES

Fracture of the nasal bones

Blunt injury to the nose may fracture the nasal bones (Figure 46.7). The fracture line can extend into the lacrimal bone and tear the anterior ethmoidal artery producing catastrophic haemorrhage. This may be delayed, occurring only as the soft tissue swelling subsides, reducing the tamponade effect on the torn vessel.

Violent trauma to the frontal area of the nose can result in a fracture of the frontal and ethmoid sinuses with potential extension into the anterior cranial fossa. Dural tears and brain injuries, either open or closed, are then at risk from sinonasal ascending infection which may progress to meningitis or brain abscess. Cerebrospinal fluid (CSF) rhinorrhoea is a certain sign of a dural tear.

Management of fractured nasal bones

Fractured nasal bones are often accompanied by extensive overlying soft tissue swelling and bruising, which may hinder the assessment of any underlying bony deformity. Reviewing after 4–5 days when the soft tissue swelling has diminished will allow a better assessment of any deformity. If there is a significant degree of nasal deformity then this can be corrected by manipulation of the nasal bones under local or general anaesthesia. This should be carried out within 10–20 days of the injury while the bony fragments are still mobile.

Septal injury

A blunt injury of moderate force may lead to lateral displacement or deformity of the septal cartilage, restricting the nasal airway. Unlike the nasal bones, the nasal septum cannot be manipulated back into position and requires a formal septoplasty

Figure 46.7 Fracture of the nasal bones with displacement of the bony nasal complex to the right side.

procedure to restore the anatomy and the patency of the nasal airways.

Bleeding under the mucoperichondrium of the septum will cause a septal haematoma and nasal obstruction. Untreated, a septal haematoma will progress to abscess formation and ultimately result in necrosis of the septal cartilage and nasal collapse. A septal haematoma should be treated by incision and evacuation of the blood clot, insertion of a small silicone drain and packing of the nasal fossa. A broad-spectrum prophylactic antibiotic should be prescribed (Summary box 46.1).

Summary box 46.1

Nasal trauma

- Do not overlook a septal haematoma
- Displaced nasal bone fractures should be reduced within 10–20 days of injury
- Severe persistent epistaxis after trauma suggests lacrimal bone fracture and injury to the anterior ethmoid artery
- Cerebrospinal fluid rhinorrhoea indicates a fracture involving the frontal or ethmoid sinuses with a dural tear

THE NASAL SEPTUM

Septal deformity

Deviation of the nasal septum may occur naturally or arise as a result of nasal trauma and is readily apparent on anterior rhinoscopy (Figure 46.8). Surgical correction can be achieved by a submucous resection (SMR) of the septum, where the deformed septal cartilage is excised while preserving a dorsal strut. The alternative is a septoplasty procedure during which the septal cartilage is preserved, but the anatomical abnormalities giving rise to its deformity, such as a twisted maxillary crest or inclination of the bony septum, are corrected.

Complications of septal surgery include septal perforation. If too much cartilage is excised in the SMR procedure, loss of support to the dorsum of the nose may result in a supratip depression or drooping of the tip of the nose.

Septal perforation

A hole in the nasal septum causes a turbulent airflow through the nose and a resulting sensation of nasal blockage and extensive nasal crusting. The causes of septal perforation are listed in Summary box 46.2.

Septal perforations seldom heal spontaneously. A great variety of operations have been described to close septal perforations, but none has met with universal success. A more certain

Figure 46.8 Coronal section through the anterior nasal fossae with deviated nasal septum to the right side.

Summary box 46.2

Causes of septal perforations

- Trauma
 - Iatrogenic following septal surgery
 - Nose picking
- Infection
 - Syphilis
 - Tuberculosis
- Vasculitis
 - Wegener's granulomatosis
- Tumours
- Toxins
 - Chrome salts
 - Cocaine
- Idiopathic

option is to occlude the perforation by inserting a Silastic biflanged prosthesis (Figures 46.9 and 46.10).

Wegener's granulomatosis is a systemic idiopathic autoimmune disease affecting the nose, lungs and kidneys. Mucosal granulations on the nasal septum destroy cartilage, producing a septal perforation with saddle deformity of the nose. Laboratory findings include a high erythrocyte sedimentation rate, impaired creatinine clearance and antineutrophil cytoplasmic antibodies (ANCA) in most cases.

Figure 46.9 Anterior and lateral views of septal perforation occluded with prosthesis.

Figure 46.10 Silastic prosthesis for septal perforation.

EPISTAXIS

The causes of epistaxis are listed in Table 46.1. The most common site of bleeding is from Kiesselbach’s plexus in Little’s area of the anterior portion of the septum (see Figure 46.6). Anterior bleeding is common in children and young adults as a result of nose blowing or picking. In the elderly, arteriosclerosis and hypertension are the underlying causes of arterial bleeding from the posterior part of the nose.

Table 46.1 Causes of epistaxis.

Local	Nose picking
	Nasal trauma
	Nasal foreign bodies
	Tumours

	Aspirin therapy
	Haemophilia
	Von Willebrand’s disease
	Leukaemia
	Haemorrhagic telangiectasia

Figure 46.11 Osler’s disease showing the multiple telangiectasia.

Hereditary haemorrhagic telangiectasia (Osler’s disease) gives rise to recurrent multifocal bleeding from thin-walled vessels deficient in muscle and elastic tissue (Figure 46.11).

Juvenile angiofibroma is an uncommon condition that affects adolescent boys and may lead to massive life-threatening episodes of bleeding. Diagnosis is made with contrast CT scanning or magnetic resonance imaging (MRI). Anterior bowing or indentation of the posterior antral wall (Holman–Miller or antral sign) is the classical finding but may be seen in other expansive lesions in this area. It is a very vascular tumour, which should not be biopsied because of the risk of uncontrollable haemorrhage. Excision is best carried out by a surgeon experienced in the management of the condition. Preoperative embolisation of the feeding blood vessels may help to reduce blood loss during surgery. Sometimes the tumour is managed with radiotherapy.

Management of epistaxis

Bleeding from Kiesselbach’s plexus may be controlled by silver nitrate cautery under local anaesthesia. Posterior bleeding, as seen in the elderly, may require anterior nasal packing either with Vaseline-impregnated ribbon gauze or absorbable sponge. An alternative to anterior packing is the use of an inflatable

epistaxis balloon catheter (Figure 46.12). The catheter is passed into the nose and the distal balloon is inflated in the nasopharynx to secure it. The proximal balloon, which is sausage shaped, is then inflated within the nasal fossa to compress the bleeding point. Although usually effective, they can be uncomfortable.

Post-nasal packing may be required in refractory cases whereby a gauze pack is positioned in the nasopharynx under general anaesthesia. Endoscopic-assisted cautery or clipping of a posterior bleeding point can be an effective alternative to nasal packing.

For uncontrolled life-threatening epistaxis in which the above methods have proved ineffective, haemostasis is secured by vascular ligation. Depending on the origin of bleeding, it may be necessary to ligate the internal maxillary artery in the pterygopalatine fossa and the anterior and posterior ethmoidal

Figure 46.12 Epistaxis balloon catheter.

Sir William Osler, 1849–1919, Professor of Medicine successively at McGill University, Montreal, Canada; the University of Philadelphia, Pennsylvania, PA, and the Johns Hopkins University, Baltimore, MD, USA, finally becoming Regius Professor of Medicine at Oxford University, Oxford, UK in 1904.

James Laurence Little, 1836–1885, Professor of Surgery, the University of Vermont, Montpelier, VT, USA.
Erik Adolf von Willebrand, 1870–1949, physician, Diakonissanstaltens Hospital, Helsinki, (Helsingfors), Finland, described hereditary pseudohaemophilia in 1926.

arteries. An alternative measure is external carotid artery ligation above the origin of the lingual artery.

In Osler's disease, anterior nasal packing is best avoided, if at all possible, because it is most likely to lead to further mucosal trauma and bleeding. High-dose oestrogen induces squamous metaplasia of the nasal mucosa and has been used effectively in treating this condition (Summary box 46.3).

Summary box 46.3

Epistaxis

- The most common causes are nose picking, hypertension and anticoagulant therapy
- Young people bleed from the anterior septum – Kiesselbach's plexus
- Elderly people bleed from the posterior part of the nose
- Silver nitrate cautery is used to control anterior bleeding
- Moderate bleeding may require anterior nasal packing
- Severe bleeding may require anterior and posterior nasal packing
- Persistent bleeding may require endoscopic cautery/clipping or arterial ligation

NASAL POLYPS

Pathology

Nasal polyps are benign swellings of the ethmoid sinus mucosa of unknown origin. Histologically, the polyps contain a waterlogged stroma infiltrated with inflammatory cells and eosinophils. The majority of nasal polyps arise from the ethmoid sinuses, with each individual ethmoid air cell giving rise to a single polyp as its swollen mucosal lining prolapses out of the air cell to hang down inside the nasal cavity. Polyps can arise from the other nasal sinuses and a single large polyp arising from the maxillary antrum is referred to as an antrochoanal polyp (Figure 46.13). This usually fills the nose and eventually prolapses posteriorly down into the nasopharynx.

Clinical features

Patients present with nasal obstruction, watery rhinorrhoea, sinus infection and often anosmia. Polyps are easily identifiable

Figure 46.13 Antrochoanal polyp.

Figure 46.14 Nasal polyp in right nasal vestibule.

within the nose as pale semitransparent grey masses, which are mobile and insensitive when palpated with a fine probe. This allows them to be distinguished from hypertrophied turbinates (Figure 46.14).

Malignancy should be considered in adults with unilateral nasal polyps, whereas in children such polyps must be distinguished from a meningocele or encephalocele by high-resolution CT scanning of the anterior cranial fossa. Nasal polyps are unusual in children. However, they do occur in conjunction with cystic fibrosis in 10 per cent of cases.

Management of nasal polyps

Medical treatment with systemic steroids will often reduce the size of nasal polyps and give short-term relief of nasal blockage. Unfortunately, the polyps tend to recur when the treatment stops. Surgical treatment is required in patients with severe nasal obstruction and pansinusitis that is refractory to medical treatment. Polyps may be removed either by avulsion with a nasal snare or endoscopically with a powered nasal microresector (Figure 46.15). After multiple recurrences, ethmoidectomy should be considered (Summary box 46.4).

Figure 46.15 Powered nasal microresector.

Summary box 46.4**Nasal polyps**

- Polyps are insensitive to touch and are mobile
- Simple polyps are bilateral
- Unilateral nasal polyps should be removed for histology
- Bleeding polyps may indicate malignancy
- Meningocele and encephalocele must be excluded in children with polyps
- Polyps can be removed with a snare or a powered microretractor
- Recurrent polyps may require ethmoidectomy
- Transitional papilloma may mimic simple nasal polyps
- All polyps should be submitted for histology

MAXILLARY SINUSITIS**Clinical features**

Local disorders, such as nasal polyps, deviated nasal septum or upper dental sepsis, may predispose to sinus infection. Patients with persistent maxillary sinusitis have a mucopurulent post-nasal discharge, headache, which is variable in severity and location, facial pain and nasal obstruction. Irritation of the superior alveolar nerve may give rise to referred upper toothache. The nasal mucosa is swollen and bathed in mucopurulent secretions. Plain sinus radiographs may show a fluid level in the antrum or complete opacity (Figure 46.16). About 10 per cent of infections of the maxillary antrum are caused by dental sepsis from anaerobic organisms. The resultant mucopurulent nasal secretion has a foul taste and smell. Complications of maxillary sinusitis include acute orbital cellulitis or osteitis.

Treatment

Adequate penetration of antibiotics into chronically inflamed sinus mucosa is doubtful and, therefore, treatment may need to

Figure 46.16 Plain radiograph showing the fluid level in the left maxillary antrum and total opacity of the right antrum.

be prolonged. Topical nasal decongestants, such as ephedrine nasal drops, will often encourage the sinus to drain.

Antral lavage under local or general anaesthesia allows confirmation of the diagnosis and provides the opportunity to obtain samples for bacteriology. The antrum is entered through the inferior meatus below the inferior turbinate where the bone separating the antrum from the nasal fossa is extremely thin and can be easily penetrated by a trocar and cannula (Figure 46.17). If infection has caused a significant degree of inflammation and fibrosis of the lining of the antrum, intranasal endoscopic techniques may be employed to create a middle meatal antrostomy or enlarge the natural ostium. Endoscopic nasal surgery allows a more functional approach to diseases of the paranasal sinuses and, as a result, the indications for radical antrostomy are decreasing (Summary box 46.5).

Summary box 46.5**Maxillary sinusitis**

- The most common causative organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*
- Anaerobic infection may result from dental sepsis
- Acute infection should be treated with antibiotics and topical decongestants
- Antral lavage is diagnostic and therapeutic
- Intranasal antrostomy or endoscopic middle meatal antrostomy may be required
- Complications of untreated infection include cellulitis, osteitis and involvement of the orbit

FRONTOETHMOIDAL SINUSITIS

Chronic frontoethmoiditis gives rise to mucopurulent catarrh, frontal headache or a feeling of pressure between the eyes, nasal obstruction and hyposmia. Nasal endoscopy will confirm pus issuing from the middle meatus. The ethmoid sinuses can only be properly assessed radiologically by CT scanning, including coronal as well as axial sections.

Complications include periorbital cellulitis (Figure 46.18). This may progress to cavernous sinus thrombosis and septicaemia. Spread of infection by direct bone penetration or via the diploic vein can give rise to extradural, subdural or frontal lobe abscess formation (Summary box 46.6).

Figure 46.17 Diagram of left maxillary antral lavage.

Figure 46.18 Left periorbital cellulitis complicating acute left ethmoiditis.

Figure 46.19 Coronal computed tomography scan showing a small osteoma in the right ethmoid sinus adjacent to the orbit.

Summary box 46.6

Frontoethmoiditis

- Assessment is best achieved by CT scanning
- It may require open surgical drainage
- Chronic infection may require an obliterative osteoplastic flap procedure
- Orbital infections may threaten sight
- Intracranial spread may cause meningitis, cerebral abscess or cavernous sinus thrombosis

TUMOURS OF THE NOSE AND SINUSES

Tumours arising in the nasal fossa may present with unilateral nasal obstruction, persistent unilateral anterior rhinorrhoea, post-nasal catarrh, epistaxis, unilateral blood-stained rhinorrhoea, facial swelling or proptosis.

Benign tumours

Simple papillomas or viral warts can grow inside the nasal vestibule. They can be confused with carcinomas and are best excised for histological diagnosis.

Osteomas of the nasal skeleton are not uncommon and are usually detected on radiography as an incidental finding (Figure 46.19). In symptomatic individuals, the osteoma can be removed via the frontal sinus or an external ethmoidectomy.

Transitional cell papillomas can occur both in the nasal cavity and the nasal sinuses. They are sometimes referred to as inverted papillomas because histologically the hyperplastic epithelium inverts into the underlying stroma. The papillomas are covered with transitional epithelium. Calcification within the tumour may be seen on CT scanning along with sclerosis of bone at the margins of the growth (Figure 46.20). Transitional cell papillomas can undergo malignant change.

Malignant tumours

The most common malignant tumours to occur within the nasal cavity and paranasal sinuses are squamous cell carcinoma (Figure 46.21), adenoid cystic carcinoma and adenocarcinoma. Adenocarcinoma has been linked to exposure to hardwood dust in the furniture industry. Adenoid cystic carcinomas arise from minor salivary glands, which can be found in the nose. Suspicious signs of invasion of neighbouring tissues include diplopia, proptosis, loosening of the teeth (Figure 46.22), trismus, cranial nerve palsies and regional lymphadenopathy (Figure 46.23).

Patients with sinus or intranasal malignancy are best managed in a combined clinic where the expertise of ear, nose and throat (ENT) surgeons, maxillofacial surgeons and radiotherapists can be employed (Summary box 46.7).

Summary box 46.7

Tumours of the nose and sinuses

- Unilateral nasal blockage, discharge and bleeding are often presenting symptoms in nasal or sinus tumours
- Osteomas are often asymptomatic
- Transitional cell papilloma is the most common benign tumour – this tumour may undergo malignant change
- Squamous cell carcinoma is the most common malignant tumour
- Almost 50 per cent of sinonasal cancers arise on the lateral nasal wall and 33 per cent in the maxillary antrum
- Multidisciplinary management of malignant sinonasal tumours requires input from ENT surgeons, maxillofacial surgeons and radiotherapists

Figure 46.20 Coronal computed tomography scan showing extensive transitional cell papilloma involving the left maxillary antrum and ethmoid sinuses.

Figure 46.21 Squamous cell carcinoma of the nasal septum.

CHAPTER 47

The ear

LEARNING OBJECTIVES

To be familiar with:

- The anatomy of the ear
- The conditions of the outer, middle and inner ear
- The examination of the ear including hearing tests

To understand that:

- The outer layer of the tympanic membrane migrates outwards

- The facial nerve can be damaged by trauma and ear disease
- Chronic ear disease can lead to intracranial sepsis
- There are two types of hearing loss: conductive and sensorineural

INTRODUCTION

The mammalian ear is an evolutionary masterpiece. Its highly complex 'three-dimensional anatomy' is best learnt by dissecting cadaver temporal bones.

SURGICAL ANATOMY OF THE EAR

The external ear

The external and middle ear develop from the first two branchial arches. The external ear canal is 3 cm in length; the outer two-thirds is cartilage and the inner third is bony. The skin on the lateral surface of the tympanic membrane is highly specialised and migrates outwards along the ear canal. As a result of this migration most people's ears are self-cleaning. The external canal is richly innervated and the skin is tightly bound down to the perichondrium so that swelling in this region results in severe pain.

The lymphatics of the external ear drain to the retroauricular, parotid, retropharyngeal and deep upper cervical lymph nodes.

The tympanic membrane and middle ear

The anatomy of the tympanic membrane and ossicles is shown in Figure 47.1. The relations of the middle ear are important (Figure 47.2).

The tympanic membrane and ossicles act as a transformer system converting vibrations in the air to vibrations within the fluid-filled inner ear.

The inner ear

The inner ear comprises the cochlea and vestibular labyrinth (saccul, utricle and semicircular canals). These structures are embedded in dense bone called the otic capsule.

The cochlea is a minute spiral of two and three-quarter turns. Within this spiral, perilymph and endolymph are partitioned by the thin Reissner's membrane. The endolymph has a high concentration of potassium, similar to intracellular fluid, and the perilymph has a high sodium concentration and communicates with the cerebrospinal fluid (CSF). Maintenance of the ionic gradients is an active process and is essential for neuronal activity.

There are approximately 15 000 hair cells in the human cochlea. They are arranged in rows of inner and outer hair cells. The inner hair cells act as mechanoelectric transducers, converting the acoustic signal into an electric impulse. The outer hair cells contain contractile proteins and serve to tune the basilar membrane on which they are positioned.

Each inner hair cell responds to a particular frequency of vibration. When stimulated, it depolarises and passes an impulse to the cochlear nuclei in the brainstem.

The vestibular labyrinth consists of the semicircular canals, utricle and saccule and their central connections. The three semicircular canals are arranged in the three planes of space at right angles to each other. Like the auditory system, hair cells are present. In the lateral canals, the hair cells are embedded in a gelatinous cupula. Shearing forces, caused by angular movements of the head, produce hair cell movements and generate action potentials. In the utricle and saccule, the hair cells are embedded in an otoconial membrane that contains particles of calcium carbonate. These respond to changes in linear acceleration and the pull of gravity.

Impulses are carried centrally by the vestibular nerve and connections are made to the spinal cord, cerebellum and extraocular muscles. Its function is to record the position and movements of the head.

The sensory nerve supply

The external ear is supplied by the auriculotemporal branch

Bartolomeo Eustachio (Eustachius), 1513–1574, was appointed physician to the Pope in 1547, and Professor of Anatomy at Rome, Italy, in 1549.

Ernst Reissner, 1824–1878, Professor of Anatomy at Dorpat, and later at Breslau, Germany (now Wrocław, Poland), described the vestibular membrane of the cochlea in 1851.

Figure 47.1 (a) Right tympanic membrane and (b) diagram to illustrate anatomy (courtesy of Dr Christian Deguine).

of the trigeminal nerve (Vth) and the greater auricular nerve (C2/3), together with branches of the lesser occipital nerve (C2). The VIIth, IXth and Xth cranial nerves also supply small sensory branches to the external ear. The middle ear is supplied by the glossopharyngeal nerve (IXth).

This complicated and rich sensory innervation means that referred otalgia is common and may originate from the normal area of distribution of any of the above nerves. A classic example is the referred otalgia caused by cancer of the larynx (Summary box 47.1).

Summary box 47.1

Applied anatomy

- The skin on the outer surface of the eardrum migrates outwards so that the ear canal is 'self-cleaning'
- Infection of the middle ear and mastoid can easily spread to the cranial cavity
- The facial nerve pursues a tortuous course through the middle ear
- The ear has a rich sensory innervation so that 'referred otalgia' is common
- Cancer of the larynx can present with otalgia

Figure 47.2 Diagram to show the relations of the middle ear (courtesy of Dr Christian Deguine). ET, Eustachian tube; M, malleus; TM, tympanic membrane; VII, facial nerve.

Taking a thorough history is the most important part of the assessment; the symptoms that need to be enquired after are listed in Table 47.1.

Table 47.1 History-taking.

Earache, pain and itch
Hearing loss
Discharge: type, quantity and smell
Tinnitus
Vertigo
Facial movements
Speech and development (in children)
Past history: head injury, baro- or noise trauma, ototoxics, family history and previous ear surgery

EXAMINATION OF THE EAR

The tools of the trade are shown in Figure 47.3. Examination of the ear is part of the general ear, nose and throat (ENT) examination. The Rinne and Weber tuning fork tests are used to distinguish between a conductive and a sensorineural hearing loss.

In Weber's test, the base of a 256Hz vibrating tuning fork is placed on the centre of the patient's forehead so that the sound is conducted through the bones of the skull (not air). If the patient hears the sound more clearly in one ear than the other, then there is either a conductive loss in that ear or neurological loss in the opposite ear. Rinne's test then distinguishes between these two possibilities. A 512-Hz tuning fork is placed on the mastoid bone until the patient can no longer 'feel' it vibrating. It is then moved so that its tips are just outside the ear. The patient should now 'hear' the sound again if conduction is normal.

The cranial nerves and especially the function of the facial nerve should be examined.

Friedrich Heinrich Adolf Rinne, 1819–1868, otologist, Göttingen, Germany, described his test in 1855.

Friedrich Eugen Weber-Liel, 1832–1891, otologist, University of Berlin and Jena, Germany. He described the operation of tenotomy of the tensor tympani used for certain forms of partial deafness.

Figure 47.3 Tools of the trade: a fiberoptic otoscope, with pneumatic attachment and a selection of specula. Also a 512-Hz tuning fork.

Although conversational testing can give a useful guide to the level of hearing, pure tone audiometry in a soundproof booth is the best way of establishing the air and bone hearing levels (Figure 47.4). Other common audiological tests include speech audiometry, tympanometry, stapedial reflexes, electric response audiometry, otoacoustic emissions, caloric testing and electro-nystagmography (see Further reading).

Radiological investigation

Computed tomography (CT) scanning of the temporal bones is routinely used preoperatively to show detailed individual anatomy, as well as alerting the surgeon to anatomical variants. Pus, bone and air are shown well on high-resolution CT (Figure 47.5).

Magnetic resonance imaging (MRI) is better than CT at imaging soft tissue (e.g. facial and auditory nerve) and is the best method for imaging tumours of the acoustic nerves (Figure 47.6).

CONDITIONS OF THE EXTERNAL EAR

Congenital anomalies

See Table 47.2.

Table 47.2 Congenital anomalies of the external ear.

The external and middle ear originate from the first and second branchial arches, but the cochlea is neuroectodermal in origin

An individual can have a congenital abnormality of the pinna and middle ear with a normal cochlea and, therefore, the potential for normal hearing.

Osseointegration allows a prosthetic ear and hearing aid to be attached to the skull

Trauma

A haematoma of the pinna occurs when blood collects under the perichondrium. The cartilage receives its blood supply from the perichondrial layer and will die if the haematoma is not evacuated, resulting in a cauliflower ear. A generous incision under general anaesthetic, with a pressure dressing or compressive sutures and antibiotic cover, is recommended (Figure 47.7).

Figure 47.4 Audiometry: the patient sits in a soundproof room and the audiologist presents sounds at different thresholds and records the responses.

Foreign bodies in the ear canal need to be treated with the greatest respect. If an object is not easily removed at the first attempt, it is better to do it with the aid of a microscope and general anaesthesia. An active two-year-old with a bead in the ear can be a formidable opponent (Figure 47.8) (Summary box 47.2).

Summary box 47.2

Trauma of the external ear

- A haematoma of the pinna requires thorough drainage, antibiotics and a compressive dressing or sutures
- Consider general anaesthesia when attempting to remove a foreign body in a young child

Inflammation and infection

Otitis externa is common and consists of generalised inflammation of the skin of the external auditory meatus. The cause is

Figure 47.5 The computed tomography scan shows a normal left ear; note the air-filled middle ear and the incus and stapes and the lateral and semicircular canals and internal acoustic meatus (IAM) can be seen. In the right ear, the entire middle ear and mastoid is opaque and filled with soft tissue. This is the typical appearance of cholesteatoma.

Celsus (AD 70) recommended tying the patient on a wooden plank with the affected ear downwards and hitting the plank with a hammer.

Figure 47.6 A high resolution T2-weighted image at the level of the internal acoustic meatus (IAM) showing an intracannalicular acoustic neuroma (AN) on the left and a normal IAM on the right (courtesy of Dr Peiter Petorius).

Figure 47.7 Haematoma of the pinna.

often multifactorial but includes general skin disorders, such as psoriasis and eczema, and trauma. Common pathogens are *Pseudomonas* and *Staphylococcus* bacteria, *Candida* and *Aspergillus*. Once the skin of the ear canal becomes oedematous, skin migration stops and debris collects in the ear canal. This acts as a substrate for the pathogens. The hallmark of acute

Figure 47.8 A foreign body seen in the ear canal, the removal of which can be a challenge (courtesy of Dr Christian Deguine).

Figure 47.9 Fungal otitis externa; note the presence of hyphae (white) and spores (black).

otitis externa is severe pain. Movement of the pinna elicits pain, which distinguishes it from otitis media.

The initial treatment is with topical antibiotics and steroid ear drops, together with analgesia. If this fails, meticulous removal of the debris with the aid of an operating microscope is required. Fungal infection can be recognised by the presence of hyphae within the canal (Figure 47.9). Fungal infection causes irritation and itch. The treatment is meticulous removal of the fungus and any debris, as well as stopping any concurrent antibiotics. Systemic antibiotics are rarely required for otitis externa but should be used if cellulitis of the pinna occurs (Figure 47.10).

Necrotising otitis externa is a rare but important condition. It presents as a severe, persistent, unilateral otitis externa in an immunocompromised individual. It is important to think of the diagnosis in an elderly diabetic patient. Usually the infecting organism is *Pseudomonas aeruginosa*. Osteomyelitis of the skull base occurs and several cranial nerves (VII, IX, X) may be destroyed by the progressing infection. Intensive systemic antibiotics are required and the disease process should be monitored by high-resolution imaging (Summary box 47.3).

Figure 47.10 Cellulitis of the pinna.

Summary box 47.3

Types of otitis externa

- Acute bacterial otitis externa is very common and extremely painful; treat with topical steroids and topical antibiotics
- Systemic antibiotics should be reserved for cellulitis of the pinna
- Chronic otitis externa needs the underlying dermatitis to be treated; application of topical steroid in spirit is recommended
- Fungal otitis externa itches and can be diagnosed by the presence of hyphae and spores; treat with meticulous cleaning and stop antibiotics
- Necrotising otitis externa is a progressive skull base infection that occurs in immunocompromised individuals and can be life-threatening; intensive long-term antibiotic treatment is required

Neoplasms

Benign osteomas arise from the bone of the ear canal in individuals who swim in cold water (Figure 47.11). No treatment is required unless the osteomas obstruct the canal. Other benign tumours include papillomas and adenomas.

Malignant primary tumours of the external ear are either basal cell or squamous cell carcinomas (Figure 47.12). Both may present as ulcerating or crusting lesions that grow slowly and may be ignored by elderly patients. Squamous cell carcinomas metastasise to the parotid and/or neck nodes. The ear canal may be invaded by tumours from the parotid gland and post-nasal space

Figure 47.11 Osteomas grow from the bony part of the ear canal in response to cold and so are found in swimmers, surfers and divers. Treatment is only required if the osteomas occlude the ear canal.

Figure 47.12 Squamous cell carcinomas of the external ear usually originate from the pinna; in this case, the tumour is growing from the canal (courtesy of Mr P Beasley).

carcinomas, which 'creep' up the Eustachian tube. All resectable malignant tumours of the ear are treated primarily with surgery, with or without the addition of radiation therapy.

CONDITIONS OF THE MIDDLE EAR

Congenital anomalies

Congenital anomalies of the middle ear may be associated with other general congenital deformities. There are a number of branchial arch syndromes, e.g. Pierre Robin's, craniofacial dysostosis, Down's and Treacher Collins' syndromes.

Trauma

Trauma to the middle ear can result in a perforated tympanic membrane (Figure 47.13a). Such perforations usually heal spontaneously (Figure 47.13b). Trauma can also result in ossicular discontinuity and it is usually the incus that is displaced. Tympanoplasty operations are available to reconstruct the

damaged ossicular chain and repair the tympanic membrane (Summary box 47.4).

Summary box 47.4

Congenital anomalies and trauma of the middle ear

- Congenital anomalies may be isolated or associated with general congenital deformities
- CT can identify middle ear abnormalities that may be corrected by surgery
- Traumatic perforations of the tympanic membrane usually heal spontaneously, but explosive and welding injuries do not
- A myringoplasty is an operation that repairs the tympanic membrane
- With severe head trauma, the incus can be displaced, which leads to a conductive hearing loss

Suppurative otitis media

Suppurative otitis media is extremely common in childhood and is characterised by purulent fluid in the middle ear. Mastoiditis may be associated with otitis media because the mastoid air cells connect freely with the middle ear space. The tympanic membrane bulges because of pressure from the pus in the middle ear (Figure 47.14). The child suffers extreme pain until the tympanic membrane bursts. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Appropriate systemic antibiotics should be given for 10 days.

Mastoiditis (Figure 47.15) requires hospital admission and intravenous antibiotics. If the infection does not resolve quickly, a cortical mastoidectomy is required, together with a myringotomy. Mastoiditis can lead to intracranial infection.

Otitis media with effusion (glue ear)

The majority of children experience at least one episode of glue ear. It is primarily thought to be caused by poor Eustachian tube function. Initially, the negative middle ear pressure results in transudation of fluid into the middle ear space (Figure 47.16). If hypoxia continues, a mucoid exudate is produced by the glands within the middle ear mucosa. This sticky exudate is referred to as 'glue ear'.

The following symptoms may be associated with glue ear:

- hearing impairment, which often fluctuates;
- delayed speech;
- behavioural problems;
- recurrent ear infections, which occur because the exudate is an ideal culture medium for micro-organisms;
- reading and learning difficulties at school.

The otoscopic findings with glue ear

The otoscopic findings of exudative glue ear are of a dull drum that is immobile on pneumatic otoscopy. The tympanic membrane is retracted and radial blood vessels may be present (Figure 47.17).

In children first presenting with bilateral glue ear, 50 per cent will be better within 6 weeks. Initially, a 'wait and watch' policy is therefore appropriate. If a bilateral conductive hearing loss persists, the child will miss out on educational opportunities

Figure 47.13 (a) Traumatically perforated tympanic membrane. (b) The same tympanic membrane 2 days later (courtesy of Dr Christian Deguine). (Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.)

Figure 47.14 Acute otitis media of the left ear; note the bulging tympanic membrane.

Figure 47.15 Child with acute mastoiditis whose tympanic membrane is shown in Figure 47.14.

Figure 47.16 The initial serous transudate of glue ear, left ear (courtesy of Dr Christian Deguine). (Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.)

and may not fulfil his or her academic potential; in these circumstances, treatment is required.

Medical treatment is of limited value. The Otovent® device may improve Eustachian tube function and is worth trying. Insertion of ventilation tubes (grommets) (Figure 47.18) and adenoidectomy are effective. The controversy is not whether surgery works, but when to intervene.

A middle ear effusion in adults is relatively rare and, when

Figure 47.17 (a) Left exudative glue ear. The tympanic membrane is dull and retracted. The light reflex has gone and there are radial blood vessels. The drum does not move with pneumatic otoscopy. (b) Right ear. Advanced exudative glue ear with retraction pockets (courtesy of Dr Christian Deguine). (Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.)

it occurs, it does not usually last long. The condition is often associated with an upper respiratory tract infection. A persistent unilateral effusion in an adult should always be viewed with suspicion. A nasopharyngeal carcinoma may cause the effusion by blocking the opening of the Eustachian tube in the post-nasal space. This is the most common carcinoma in men in southern China (Summary box 47.5).

Summary box 47.5

Acute suppurative otitis media and glue ear

- Acute suppurative otitis media can progress to mastoiditis
- Glue ear is very common in children and usually resolves without treatment
- Persistent hearing loss and/or recurrent acute otitis media is best treated with grommets and/or an adenoidectomy
- A persistent middle ear effusion in an adult is rare and may be caused by a cancer of the post-nasal space, especially in Chinese and Asian races

Figure 47.18 Ventilation tube in tympanic membrane, left ear (courtesy of Dr Christian Deguine).

Chronic suppurative otitis media

Chronic suppurative otitis media (CSOM) may involve the pars tensa and the middle ear and is referred to as tubotympanic disease; it results from trauma or infection. When perforated, the tympanic membrane usually repairs itself, but if the outer layer of the tympanic membrane fuses with inner mucosa a chronic perforation results (Figure 47.19). The patient's main symptoms are of an intermittent mucoid discharge associated with a mild

Figure 47.19 (a) Tubotympanic chronic suppurative otitis media showing central perforation, right ear. (b) Anatomy (courtesy of Dr Christian Deguine).

conductive hearing loss. It is rare for this type of disease to be associated with intracranial complications.

A diagnosis is made on otoscopy and the tuning forks usually suggest a conductive hearing impairment. The first-line treatment is topical antibiotics and steroid drops and, on occasion, microsuction. If medical treatment fails, it may be necessary to graft the tympanic membrane.

Atticoantral CSOM (often associated with cholesteatoma) is important because of the complications associated with it. A retraction pocket develops in the pars flaccida and, if the squamous epithelium cannot migrate out of this pocket, a cholesteatoma results. A low-grade osteomyelitis gives the discharge its characteristic faecal smell. Invariably, the discharge is accompanied by hearing loss and mild discomfort. The patient may simply put up with these symptoms until a severe complication occurs.

The hearing loss that is caused by cholesteatoma may be conductive as a result of ossicular erosion or sensorineural as a result of cochlea damage. Vestibular symptoms may occur because of erosion of the semicircular canals or the migration of toxins into the vestibule. Erosion of the facial nerve is relatively unusual.

The close proximity of the middle ear and mastoid to the middle and posterior cranial fossae means that intracranial sepsis can result from chronic ear disease. The infection spreads to the dura via emissary veins, which connect the middle ear mucosa to the dura, or by direct extension of the disease through the bone. Meningitis, extradural, subdural or intracerebral abscess, or a combination of these may occur. Diagnosis should be suspected on otoscopy (Figure 47.20). Pus, crusts, granulations or a whitish debris in the attic are hallmarks of the disease. Examination under the microscope, audiometry and, sometimes, CT scanning are indicated.

The treatment is surgical and follows the principle of exposing the disease, excising the disease and then exteriorising the affected area. Three commonly applied operations for this disease are an atticotomy, modified radical mastoidectomy or combined approach tympanoplasty (Summary box 47.6).

Summary box 47.6

Chronic suppurative middle ear disease

- Tubotympanic CSOM, in which there is a hole in the eardrum and frequently a mucoid discharge; this is seldom serious
- Atticoantral CSOM (cholesteatoma). In this condition, squamous epithelium has invaded a retraction pocket in the attic part of the eardrum and is known as a cholesteatoma. Presents with hearing loss and faecal smell from the ear. It is a common cause of intracranial sepsis

Tuberculous otitis media

This is an important cause of suppuration in many countries. The diagnosis should always be considered in any ear that fails to respond to standard therapy.

Otosclerosis

This is a condition in which new abnormal spongy bone is laid down in the temporal bone. Of particular importance is the bone that is laid down around the footplate of the stapes, which

impedes the mobility of the stapes and results in a conductive hearing loss (Figure 47.21). A diagnosis should be suspected in any patient with a conductive hearing loss and a normal tympanic membrane.

A similar type of stapes fixation occurs in osteogenesis imperfecta and is known as van der Hoeve's syndrome. Otosclerosis is often bilateral.

The treatment options are simple reassurance, a hearing aid or a stapedotomy operation (Figure 47.22).

Neoplasms

Middle ear tumours are rare with the most common being a glomus tumour (Figure 47.23). Glomus tumours arise from non-chromaffin paraganglionic tissue. The carotid body tumour arising in the neck is an example of this type of tumour. In the temporal bone, three types of glomus tumour are recognised and classification depends on the location: glomus tympanicum (arising in the middle ear), glomus jugularae (arising next to the jugular bulb) and glomus vagali (skull base).

Pulsatile tinnitus is a classic symptom and the hearing loss that occurs may be either conductive or sensorineural. Palsies of the VIIth, IXth, Xth, XIth and/or XIIth nerves may occur. The classic sign is a cherry-red mass lying behind the tympanic membrane. An audible bruit may be heard with a stethoscope over the temporal bone. The treatment of choice is preoperative embolisation followed by surgical excision. Radiotherapy is also effective.

Squamous cell carcinoma may also occur within the middle ear. It usually presents with deep-seated pain and a blood-stained discharge. Facial paralysis often occurs. Squamous carcinomas usually arise in a chronically discharging ear and can arise in a chronically infected mastoid cavity. Radical surgical excision, with or without radiotherapy, provides the only chance of cure (Summary box 47.7).

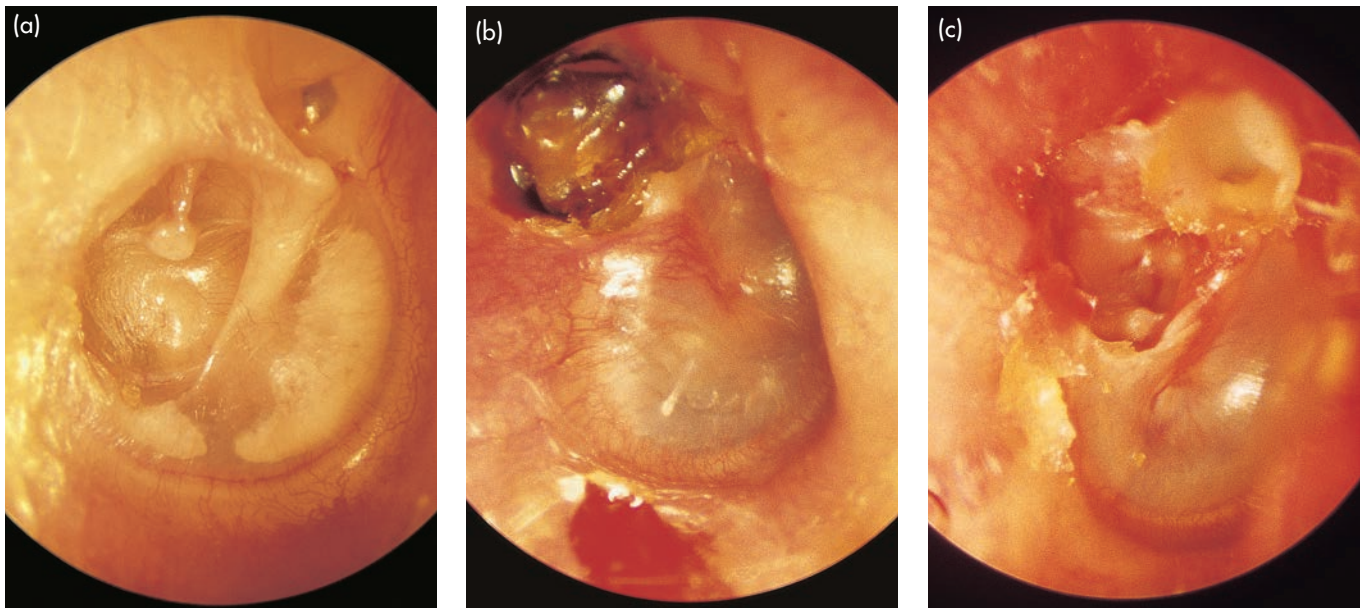

Figure 47.20 (a) Empty attic retraction pocket, right ear. (b) Attic crust covering cholesteatoma, right ear. (c) Attic erosion with cholesteatoma, right ear.

Figure 47.22 The stapedotomy operation showing the piston linking the incus to the vein graft, left ear.

Summary box 47.7

Neoplasms of the middle ear

- Highly vascular glomus tumours are rare and may present with pulsatile tinnitus
- Squamous cell cancer usually presents with pain and facial paralysis

CONDITIONS OF THE INNER EAR

Congenital anomalies

Congenital inner ear disorders may be associated with external or middle ear abnormalities or exist on their own. The most common anomaly is dysplasia of the membranous labyrinth, although dysplasia of the bony labyrinth and even total aplasia of the ear may occur. Intrauterine infections, including rubella, toxoplasmosis and cytomegalovirus infection, can cause inner ear damage. Perinatal hypoxia, jaundice and prematurity are also risk factors for a hearing loss. After birth, meningitis may cause profound sensorineural hearing loss.

If a child's parents suspect a hearing impairment, it is important to believe them, especially when glue ear has been excluded. In children in whom there is a suspicion of sensorineural hearing loss, brainstem-evoked audiometry is used to establish hearing thresholds (Figure 47.24). If some hearing is present, the early fitment of hearing aids can maximise the neural plasticity that is present in the developing brain. If a child has a profound hearing loss, early intervention with a cochlear implant is the ideal solution (Figure 47.25). Most cases of profound sensorineural hearing loss are due to loss of cochlear hair cells, so that an implant inserted through the round window can selectively stimulate the cochlear neurones, which usually remain intact. The results of cochlear implantation are miraculous but it is expensive technology.

Figure 47.23 Glomus tumour in the middle ear, left ear.

Figure 47.24 Evoked-response audiometry. A simple non-invasive objective test of hearing thresholds. (Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.)

Figure 47.25 Multichannel cochlear implant (Cochlear Corporation).

Figure 47.26 Typical audiogram of presbycusis: (a) right ear; (b) left ear.

Figure 47.27 A tinnitus masker.

Presbycusis

Presbycusis is characterised by a gradual loss of hearing in both ears, with or without tinnitus. The hearing loss usually affects the higher frequencies and a classical audiogram is shown in Figure 47.26. The consonants of speech lie within the high-frequency range, which makes speech discrimination difficult.

Many patients with presbycusis are concerned that they may lose their hearing completely and they need reassurance. Hearing aid technology has improved dramatically and most patients can benefit.

Tinnitus

Tinnitus is an abnormal noise that appears to come from the ear or within the head. It may have an extrinsic cause, for example the pulsatile tinnitus of a glomus tumour. Usually, however, the tinnitus is generated within the cochlea. Most people will experience tinnitus at some time in their lives. Tinnitus frequently accompanies presbycusis, as well as any other condition that damages the inner ear structures. Most individuals adapt to the presence of tinnitus, but in some patients it proves intrusive. Reassurance and relaxation therapy are highly effective as are

hearing aids for patients who also have presbycusis. An ENT surgeon who was a keen fisherman found that he could not hear his tinnitus when fishing next to a waterfall. From this observation, tinnitus maskers were developed (Figure 47.27). A masker provides a similar noise to the tinnitus and 'blanks it out'.

Trauma

Noise exposure

Hair cells within the cochlea are damaged by sudden acoustic trauma (blast injury or gunfire) or prolonged exposure to excessive noise. The sensorineural hearing loss that results is greatest at high frequencies (particularly 4000 Hz) and is often accompanied by tinnitus (Figure 47.28). The law in the UK requires that workers are protected from noise, but in a disco an individual relies on common sense!

Head injury

The otic capsule is the hardest bone in the body but, if trauma to the head is severe, temporal bone fractures may occur. These tend to be either longitudinal (80 per cent) or transverse (20 per cent). Transverse fractures usually involve the labyrinth and lead to a sensorineural hearing loss that is permanent. Profound vertigo occurs initially, followed by gradual compensation. In about 50 per cent of cases, there is an associated facial nerve paralysis.

Drug ototoxicity

Certain drugs differentially affect the cochlea, causing hearing loss and tinnitus, whereas others affect the vestibular system, causing vertigo. Aminoglycosides are well known to be ototoxic, as is cis-platinum. Recognition of risk factors, such as poor renal function in patients being treated with aminoglycosides, is most important. Although many topical ear drops contain aminoglycosides, there is little evidence that such topical treatment causes sensorineural hearing loss if used for short periods.

Figure 47.28 A typical audiogram of noise damage: (a) right ear; (b) left ear.

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) may follow head or neck trauma. Vertigo is an illusion of movement and BPPV is characterised by intermittent attacks of vertigo that occur when the head is moved in a certain position. Typically, the vertigo only lasts for a few seconds and is not associated with other otological symptoms. Positional testing can evoke nystagmus and helps in the diagnosis of this condition. The condition is usually self-limiting, and special manoeuvres described by Epley help the majority of patients.

Reduction in cochlear blood flow

This is the most likely cause for most cases of sudden onset of severe sensorineural hearing loss. Five per cent of patients with an acoustic neuroma present with sudden sensorineural hearing loss and, therefore, radiological investigation is required to exclude this diagnosis.

Inflammation

Viral infections are thought to account for acute vestibular failure. This condition is characterised by a sudden onset of vertigo. The vertigo is so severe that the patient goes to bed for 5 days. Central compensation then occurs, although recurring episodes of vertigo can occur for up to 18 months.

Menière's disease

The aetiology is not known but the pathology is well documented. There is an excessive accumulation of endolymphatic fluid (hydrops) and it is thought that the distension of the endolymphatic compartment may rupture Reissner's membrane, which leads to mixing of endolymph and perilymph. The condition is characterised by a triad of symptoms: intermittent attacks of vertigo, a fluctuating sensorineural hearing loss and tinnitus. The patient often has a sensation of pressure in the affected ear

before an attack. The hearing loss typically affects the lower frequencies. The vertigo characteristically lasts between 30 minutes and 6 hours and is often accompanied by nausea and vomiting. The investigations include pure tone audiometry, electrocochleography and an MRI scan to exclude an acoustic neuroma. Medical treatment with betahistadine and diuretics is effective, with selective destruction of the vestibular labyrinth by percolating gentamicin through a grommet being reserved for resistant cases.

Facial paralysis

Viral infections that involve the facial nerve are one of the most common causes of facial weakness (80 per cent). Bell's palsy results from a viral infection of the facial nerve. The nerve swells and is compressed within the temporal bone. Early treatment with high-dose steroids is appropriate. Not all facial nerve palsies are due to viral infection and a thorough otoneurological examination is required. The facial nerve can be damaged at the cerebellopontine angle, within the internal auditory meatus, within the middle ear, at the skull base and within the parotid gland. It is essential to consider these potential sites of facial nerve damage in any patient with VIIth nerve paralysis (Summary box 47.8).

Summary box 47.8

Facial paralysis

- The facial nerve passes through the middle ear and mastoid
- When considering a paralysis, think 'complete' or 'partial'
- Protect the eye: carry out a full otoneurological examination to find the cause
- If acute, consider steroids and antiviral agents

Prosper Menière, 1799–1862, physician, Institute for Deaf Mutes, Paris, France, described this condition in 1861.

Sir Charles Bell, 1774–1842, surgeon, The Middlesex Hospital, London, UK (1812–1835), and later Professor of Surgery, the University of Edinburgh, Scotland, UK (1836–1842).

John W Epley, contemporary, Director, Portland Otolaryngology Clinic, Portland, Oregon, USA, established his clinic in 1975; he developed the Epley manoeuvre for treating benign paroxysmal positional vertigo.

Figure 47.29 Herpes zoster infection of the VIIth (a) and VIIIth (b) nerves with vesicles on the pinna.

Ramsay Hunt syndrome

This is caused by herpes zoster and is characterised by facial paralysis, pain and the appearance of vesicles on the tympanic membrane, ear canal and pinna (Figure 47.29). It is accompanied by vertigo and sensorineural hearing loss (VIIIth nerve). Treatment with aciclovir is effective if given early.

The metabolic causes of inner ear damage

These include diabetes mellitus and thyroid disease, both of which may cause sensorineural hearing loss.

Neoplasms

These are uncommon but can present with sensorineural hearing loss, tinnitus and vertigo. Acoustic neuromas, which are actually schwannomas of the vestibular division of the VIIIth nerve, are the most common, followed by meningiomas. Acoustic neuromas grow slowly and somewhat unpredictably and as they expand can cause cranial nerve palsies, brainstem compression and raised intracranial pressure. The early symptoms are a unilateral sensorineural hearing loss or unilateral tinnitus, or both. It is important to diagnose these tumours early and remove them when they are small. The morbidity and mortality from surgery is directly related to tumour size. If the tumour is removed when it is small, there is an extremely good chance of preserving facial nerve function.

The investigation of choice for detecting acoustic neuromas is MRI. The treatment options include a 'wait and see' policy, which may be appropriate for an elderly patient with minimal symptoms. MRI can be used to monitor the tumour (Summary box 47.9).

Summary box 47.9

Conditions of the inner ear

- Presbycusis is the bilateral high-frequency loss associated with ageing
- Unilateral tinnitus or sensorineural hearing loss needs to be investigated to exclude acoustic neuroma
- Sudden sensorineural hearing loss needs immediate treatment, and radiological investigation in the case of acoustic neuroma
- Menière's disease presents with the triad of sensorineural hearing loss, tinnitus and vertigo

LEARNING OBJECTIVES

To understand:

- The relevant anatomy, physiology, disease processes and investigations of the pharyngolarynx and neck
- The diagnosis and emergency treatment of airway obstruction

- The aetiology, natural history, management and prevention of squamous carcinoma of the upper aerodigestive tract

CLINICAL ANATOMY AND PHYSIOLOGY

The pharynx

The pharynx is a fibromuscular tube forming the upper part of the respiratory and digestive passages. It extends from the base of the skull to the level of the sixth cervical vertebra at the lower border of the cricoid cartilage where it becomes continuous with the oesophagus. It is divided into three parts: the nasopharynx, oropharynx and hypopharynx (Figure 48.1).

Nasopharynx

The nasopharynx lies anterior to the first cervical vertebra and has the openings of the Eustachian tubes in its lateral

wall, behind which lie the pharyngeal recesses, the fossae of Rosenmüller. The adenoids are situated submucosally at the junction of the roof and posterior wall of the nasopharynx.

Oropharynx

This is bounded above by the soft palate, below by the upper surface of the epiglottis and anteriorly by the anterior faucial pillars. The oropharynx contains the palatine tonsils situated in the lateral wall between the anterior and posterior pillars of the fauces. They are part of the complete ring of lymphoid tissue (Waldeyer's ring) together with the adenoids and lingual tonsils on the posterior third of the tongue. This ring of lymphoid tissue occupying the entry to the air and food passages is constantly exposed to new antigenic stimuli and is an important part of the mucosa-associated lymphoid tissues (MALT), which process antigen and present it to T helper cells and B cells (Figure 48.2).

The tissue of Waldeyer's ring undergoes physiological hypertrophy during early childhood as the child is exposed to

Figure 48.1 The component parts of the pharynx.

Figure 48.2 Waldeyer's ring.

increasing amounts of antigenic stimuli, and there is often a similar hypertrophy of the cervical lymph nodes.

It also has an exceptionally good blood supply from the facial artery, which may be closely related to the lower pole, and laterally a plexus of paratonsillar veins, which may be the source of serious venous bleeding following tonsillectomy.

Hypopharynx

The hypopharynx is bounded above and anteriorly by the sloping laryngeal inlet. Its inferior border is the lower border of the cricoid cartilage where it continues into the oesophagus. The hypopharynx is commonly divided into three areas: the pyriform fossae, the posterior pharyngeal wall and the post-cricoid area. The mucosa of these areas is, however, continuous so disease processes, such as squamous carcinoma, can easily involve more than one area and may also spread submucosally. The motor nerve supply of the pharynx and larynx is the vagus nerve.

Understanding of the physiology of normal swallowing and the problems caused by disease has been enhanced in the last two decades by the use of videofluoroscopy in which the passage of a bolus of radio-opaque liquid or solid from the point at which it enters the oral cavity down to its passage within the stomach is examined radiologically. It is considerably more accurate than a barium swallow.

Swallowing is mediated via efferent fibres passing to the medulla oblongata through the second division of the trigeminal nerve (V), glossopharyngeal nerve (IX) and vagus nerve (X) (Figure 48.3). The afferent pathway is from the nucleus ambiguus and is mediated via the glossopharyngeal (IX), vagus (X) and hypoglossal (XII) nerves. Damage to these major cranial nerves at any point along their pathway, by trauma or disease, may cause dysphagia with or without aspiration.

The main function of the larynx is not the production of voice but the protection of the tracheobronchial airway and lungs; it closes completely during swallowing.

RELATIONS OF THE PHARYNX

Some of these are illustrated in Figure 48.4.

Parapharyngeal space

This potential space lies lateral to the pharynx and extends from the base of the skull above to the superior mediastinum below. It is occupied by the carotid vessels, internal jugular vein, deep cervical lymph nodes, the last four cranial nerves and the cervical sympathetic trunk.

Infection and suppuration of the cervical lymph node in the parapharyngeal space most commonly occurs from infections of the tonsils or teeth (particularly the third lower molar tooth). It may then spread up to the skull base or down to the paraoesophageal region and superior mediastinum.

Retropharyngeal space

This potential space lies posterior to the pharynx, bounded anteriorly by the posterior pharyngeal wall and its covering buccopharyngeal fascia and posteriorly by the cervical vertebrae and their covering muscles and fascia. It contains the retropharyngeal lymph nodes, which are usually paired lateral nodes but which are separated by a tough median partition that connects the prevertebral with the buccopharyngeal fascia.

These nodes are more developed in infancy and young

Figure 48.3 The three phases of swallowing (a) and the muscles involved (b).

Figure 48.4 Sagittal diagram of upper aerodigestive tract.

children, and it is at this age that they are most likely to be involved in inflammatory processes, which, if severe, may affect swallowing and respiration as a consequence of gross swelling and suppuration of the retropharyngeal space.

Larynx

The larynx is the protective sphincter that closes off the airway during swallowing and, in humans and some other mammals, is responsible for the production of sound. The larynx has a mainly cartilaginous framework that may ossify in later life, and which consists of the hyoid bone above, the thyroid and cricoid cartilages and the intricate arytenoid cartilages posteriorly.

The cricoid cartilage is the only complete ring in the entire airway and bounds the subglottis, which is the narrowest point of the airway. This is the most common site for damage from an endotracheal tube used for intensive care unit ventilation in seriously ill patients.

An anatomical description of the larynx divides it into the supraglottis, glottis and subglottis (Figure 48.5). The true vocal folds (often incorrectly called the vocal cords) are normally white in contrast to the pink mucosa of the rest of the larynx and airway. The true vocal folds meet anteriorly at the midlevel of the thyroid cartilage, whereas posteriorly they are separate and attached to an arytenoid cartilage. This arrangement produces the 'V' shape of the glottis (Figure 48.6).

Figure 48.5 Anatomy of the larynx. (Reprinted from Aird's Companion in Surgical Studies, 2nd edn, Burnand, K.G. and Young, A.E. (eds), 1998, Fig. 20.37, with permission from Elsevier.)

Nerve supply

The sensory nerve supply to the larynx above the vocal folds is from the superior laryngeal nerve and below the vocal folds is from the recurrent laryngeal nerve. Both these nerves are branches of the vagus nerve (X). The motor nerve supply to the larynx is from the recurrent laryngeal nerve, which is a branch of the vagus nerve and which supplies all intrinsic muscles. Only one of these intrinsic muscles, the posterior cricoarytenoid, abducts the vocal folds during respiration. All other intrinsic muscles adduct the cords. As all of the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve, damage to this nerve or to the vagus nerve will cause paralysis of the vocal fold on the side of the damage.

Views on indirect laryngoscopy

(a) Vocal folds abducted (open)

(b) Vocal folds adducted (closed)

Figure 48.6 A view of the larynx on indirect laryngoscopy: (a) vocal folds abducted; (b) vocal folds adducted. (c) Photograph of normal larynx in abduction. (Adapted from Aird's Companion in Surgical Studies, 2nd edn, Burnand, K.G. and Young, A.E. (eds), 1998, Fig. 20.38, with permission from Elsevier.)

Phonation/speech

The larynx functions by closing the vocal fold against the air being exhaled from the lungs, but the rise in subglottic pressure forces the vocal folds apart slightly for an instant of time with accompanying vibration of the vocal fold epithelium. The opening and closing occurs in rapid sequence to produce a vibrating column of air, which is the source of sound.

Paralysis or disease of the vocal folds or closely associated laryngeal structures will give rise to disturbance of the sound, producing hoarseness.

The functions of the larynx are given in Summary box 48.1.

Summary box 48.1

Functions of the larynx

Protection of the lower respiratory tract by

- Closure of the laryngeal inlet
- Closure of the false cords
- Closure of the glottis
- Cessation of respiration
- Cough reflex

Phonation

- Vocal folds produce sound by quasi-periodic vibration

Respiration

- Control of pressure

Fixation of chest

- Aids lifting, straining and climbing

The neck

The neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle. The anterior triangle extends from the inferior border of the mandible to the sternum below, and is bounded by the midline and the sternocleidomastoid muscle. The posterior triangle extends backwards to the anterior border of the trapezius muscle and inferiorly to the clavicle. The upper part of the anterior triangle is commonly subdivided into the submandibular triangle above the digastric muscle and the submental triangle below. The lymphatic drainage of the head and neck is of considerable clinical importance (Figure 48.7). The most important chain of nodes are the jugular nodes (also called cervical), which run adjacent to the internal jugular vein. The other main groups are the submental, submandibular, pre- and post-auricular, occipital and posterior triangle nodes.

A system of levels is used to describe the location of these neck nodes (Figure 48.8). The upper jugular nodes, level II, which contain the large jugulodigastric node, drain the naso- and oropharynx, including the tonsils, posterolateral aspects of the oral cavity, and the superior aspects of the larynx and pyriform fossae. They are the most common site of enlargement and may be palpated along the anterior border of the sternocleidomastoid muscle.

Metastatic spread of squamous cell carcinoma (80 per cent of head and neck cancer) most commonly occurs with tumours of the nasopharynx, tongue base, tonsil, pyriform fossae and supraglottic larynx. When an enlarged neck node is detected and malignant disease is suspected, these five primary sites must be carefully examined.

Figure 48.7 Distribution of cervical lymph nodes.

Figure 48.8 The level system for describing location of lymph nodes in the neck. Level I, submental and submandibular group; level II, upper jugular group; level III, middle jugular group; level IV, lower jugular group; level V, posterior triangle group; level VI, anterior compartment group.

CLINICAL EXAMINATION

Pharynx and larynx

Before examination of the pharynx, the oral cavity should be examined with the aid of a good light and tongue depressors. A reflecting mirror on the head or a headband-mounted fiberoptic light source permits use of both hands to hold instruments. Inspection should include the buccal mucosa and lips, the palate, the tongue and floor of the mouth, all surfaces of the teeth and gums, opening and closing of the mouth and dental occlusion. Patients should be asked to elevate the tongue to the roof of the mouth and protrude the tongue to both the right and the left. Palpation may be required using one or two fingers gently intraorally to feel any swellings and this may be combined with extraoral palpation of the submental and submandibular lymph nodes and salivary glands.

Following examination of the oral cavity, the oropharynx is

then inspected with the tongue depressor placed firmly onto the tongue base to depress it inferiorly. The anterior and posterior faucial pillars, the tonsil, retromolar trigone and posterior pharyngeal wall should all be inspected for colour changes, ulceration, pus, foreign bodies and swellings. Even with an experienced examiner, approximately one-third of patients cannot tolerate the depression of the posterior base of tongue without gagging. Pain and trismus as a consequence of pharyngolaryngeal or neck pathology may additionally add to the difficulty of the examination.

Fibreoptic endoscopes passed through the nose or through the mouth, with or without topical anaesthesia, allow high-quality examination of the entire nasopharynx, oropharynx and larynx in almost every patient.

The neck

The patient should be examined sitting with the whole neck exposed so that both clavicles are clearly seen. The neck is inspected from in front and the patient asked to swallow, preferably with the aid of a sip of water. Movements of the larynx and any swelling in the neck are noted. The patient should be asked to protrude the tongue if there is a midline neck swelling. A thyroglossal cyst will move upwards with the tongue protrusion. The patient is then examined from behind with the chin flexed slightly downwards to remove any undue tension in the strap muscles, platysma and sternocleidomastoids. The neck is palpated bilaterally in a sequential manner comparing the two sides of the neck.

On examining for a lump in the neck, it is often helpful to ask the patient to point to the lump first. Ask if the lump is tender. A swelling beneath the sternomastoid muscle may be considerably larger than thought on palpation. If malignancy is suspected (hard, irregular or fixed to overlying skin or to deep structures), inspection of the nasopharynx, tonsils, tongue base, pyriform fossae and supraglottic larynx is essential (Summary box 48.2).

INVESTIGATIONS OF THE PHARYNX, LARYNX AND NECK

Plain lateral radiographs

Plain lateral radiographs of the neck and cervical spine may show soft tissue abnormalities; of particular importance is the depth and outline of the prevertebral soft tissue shadow. The outline of the laryngotracheal airway may be a useful guide to the presence of disease in the pharynx and larynx (Figure 48.9).

There should be no air within the upper oesophagus. If air is seen, endoscopy is advised. Radio-opaque foreign bodies may be seen impacted in the pharynx, larynx or upper oesophagus on these radiographs.

Barium swallow

Barium liquid video fluoroscopic studies record the movement of a small quantity of radio-opaque liquid and allow detailed evaluation of the oral and pharyngeal phases of swallowing (Figure 48.10).

Computed tomography scanning

Computed tomography (CT) scanning provides much improved demonstration of disease in the pharynx, larynx and neck. Intravenous contrast given at the same time as the CT scan

Summary box 48.2

Key points of history and examination

Mouth

- Adequate light source and two spatulas to examine the mouth
- Examine
 - Teeth, gums, gingival sulci
 - Buccal mucosa, opening of parotid duct
 - Floor of mouth
 - Hard and soft palates
 - Retromolar trigone region ('coffin corner')
 - Anterior and posterior faucial pillars, tonsils
 - Posterior pharyngeal wall
 - Tongue (observe full movements)

Palpate

Salivary glands/ducts

Larynx, oropharynx and hypopharynx

- Indirect laryngoscopy
 - Mirror and headlight
- Direct flexible fibreoptic pharyngolaryngoscopy

Nasopharynx

- Rigid Hopkins' rod endoscopy
- Flexible fibreoptic nasendoscopy

Neck

Inspection

Tongue protrusion
Observe swallowing

Palpation

If a mass is palpable, evaluate for size, site, shape, consistency, superficial and deep fixation, fluctuation, transillumination, auscultation

Figure 48.9 Plain lateral radiograph showing normal anatomy.

Figure 48.10 Videofluoroscopy image showing liquid barium in the upper pharynx in a normal swallow.

(dynamic scanning) further improves the demonstration of disease in these areas (Figure 48.11).

Other imaging

Magnetic resonance imaging (MRI) may be used to give better soft tissue definition of some diseases, however, bony and cartilaginous structures are less well defined (Figure 48.12). MRI is more vulnerable to movement artefact. Ultrasound scanning can be useful in differentiating solid lesions, e.g. malignant lymph nodes from cystic lesions such as a branchial cyst.

Fine-needle aspiration cytology

This technique can be performed under local anaesthesia. It is useful particularly if a neck lump is thought to be malignant. Increasingly high rates of accurate histological diagnosis are reported and there is no evidence of spread of tumour through the skin track caused by the fine hypodermic needle used with this technique. Flow cytometry should be undertaken if haematological malignancy, such as lymphoma, is suspected. Fine-needle aspiration is considerably aided by ultrasound or CT guidance.

Angiography or digital subtraction vascular imaging

These may be indicated if a vascular lesion, such as a carotid body tumour, is suspected. Angiography may have a therapeutic role to play by facilitating embolisation of the lesion.

Direct pharyngoscopy and laryngoscopy

Examination of the pharynx, larynx and neck under general anaesthesia may be required if there are problems with the routine examination of patients, such as an inadequate view as a result of trismus from pain, poor patient compliance or large obstructive pharyngeal or laryngeal pathology. These examinations may be further aided by the use of an operating microscope or rigid endoscope (Hopkins' rod) (Figure 48.13).

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, University of Reading, Reading, UK. He invented the rigid rod endoscope (Hopkins' rod, 1954), and contributed to the development of the fibres for flexible endoscopes.

Figure 48.11 Axial computed tomography scan through the larynx at the level of the glottis.

Figure 48.12 Axial magnetic resonance imaging scan at the same level as Figure 48.11.

Figure 48.13 A rigid Hopkins' rod or endoscope.

The advantages and disadvantages of laryngeal examination techniques are given in Summary box 48.3.

Summary box 48.3**Advantages and disadvantages of larynx and pharynx examination techniques****Flexible nasendoscopy**

- Well-tolerated examination
- Can also examine nasal passages and post-nasal space
- Need fiberoptic light source

Rigid endoscopy

- Can be used with stroboscope for evaluation of voice
- High definition view
- Needs fiberoptic light source
- Bulky and difficult if prominent gag reflex present

Laryngeal mirror

- Does not need fiberoptic light source
- No record of exam, small image

DISEASES OF THE PHARYNX**Nasopharynx****Enlarged adenoid**

The most common cause of an enlarged adenoid (there is only one nasopharyngeal adenoid, despite the common use of the term 'adenoids') is physiological hypertrophy. The size of the adenoid alone is not an indication for removal. It is often associated with hypertrophy of the other lymphoid tissues of Waldeyer's ring. If excessive hypertrophy causes blockage of the nasopharynx in association with tonsil hypertrophy, the upper airway may become compromised during sleep causing obstructive sleep apnoea.

Obstructive sleep apnoea

This condition is becoming increasingly diagnosed and is important because it can cause sleep deprivation and secondary cardiac complications. It has been implicated in some cases of sudden infant death syndrome. The most common symptom is snoring, which is typically irregular, with the child actually ceasing respiration (apnoea) and then restarting with a loud inspiratory snort. The child is often restless and may take up strange sleep positions as he or she tries to improve the pharyngeal airway. Surgical removal of the tonsils and adenoid is curative, but it is important to avoid sedative premedications and opiate analgesics postoperatively because they may further depress the child's respiratory drive.

Obstructive sleep apnoea (OSA) may also occur in adults, where the obstruction may result from nasal deformity, a hypertrophic soft palate associated with an altered nasopharyngeal isthmus, obesity and general narrowing of the pharyngeal airway, or supraglottic laryngeal pathology. Initial investigation may include a sleep study, during which measurement of the patient's sleep pattern and arterial oxygenation are undertaken. Continuous positive airways pressure (CPAP) devices may ameliorate OSA by splinting the obstruction open. Surgery may also be indicated, depending on the level(s) of the obstruction.

Hypertrophy of adenoid tissue most commonly occurs between the ages of four and ten, but the adenoid tissue usually undergoes spontaneous atrophy during puberty, although some

remnants may persist into adult life (Figure 48.14). The relationship of adenoid enlargement to recurrent secretory otitis media or recurrent acute otitis media is not entirely clear.

Adenoidectomy

Adenoid tissue can be removed alone or in conjunction with a tonsillectomy. The indications for adenoidectomy are:

- obstructive sleep apnoea associated with post-nasal obstruction;
- post-nasal discharge;
- recurrent acute otitis media or prolonged serous otitis media, usually longer than three months' duration;
- recurrent rhinosinusitis.

Removal of the adenoid

Operative technique. The adenoid tissue is removed with a guarded curette pressed against the roof of the nasopharynx and then carried downwards in a moderately firm sweeping movement bringing the excised adenoid into the oropharynx (Figures 48.15 and 48.16). The guard on the curette secures the adenoid and prevents it from dropping inferiorly into the airway. A

Figure 48.14 Plain lateral radiograph showing a large pad of adenoid tissue (arrow) in the postnasal space.

Figure 48.15 St Clair Thomson's adenoid curette.

Figure 48.16 Curettage of the adenoid.

post-nasal swab is placed into the nasopharynx until all haemorrhage has ceased. A mirror can be used to guide the direction of the adenoid curette. Alternatively, suction monopolar diathermy may be used to remove adenoid tissue.

Reactionary or secondary haemorrhage during the recovery period may require a nasopharyngeal pack under a further anaesthetic. This can occasionally cause respiratory depression in children and adults, and strict observation is required while the pack is in place.

TUMOURS OF THE NASOPHARYNX

Benign

There are two main types of benign tumour of the nasopharynx: the angiofibroma and the antrochoanal polyp. Both are rare.

Angiofibroma

This tumour is confined to young male patients, most commonly between the ages of 8 and 20 years. It usually causes progressive nasal obstruction, recurrent severe epistaxis, purulent rhinorrhoea and, occasionally, loss of vision because of compression of the optic nerve. Although the tumour is rare, these symptoms in a young male patient should always arouse suspicion. The tumour is most common in northern India, although the reasons for this are unknown. Clinical examination often shows a tumour in the nasal cavity or nasopharynx, but CT scanning best demonstrates the extent of the tumour and its accompanying bony erosion. MRI scanning defines the soft tissue extent and, with these two modern investigations, angiography is rarely indicated. Biopsy should be avoided unless clinical and radiological examinations are not diagnostic because of the risk of bleeding.

Surgical resection requires adequate exposure either through a midfacial approach or lateral rhinotomy (Figures 48.17 and 48.18). Both allow ligation of the feeding maxillary artery. More recently, endoscopic resection has been used for smaller lesions.

Antrochoanal polyp

This relatively uncommon lesion is a benign mucosal polyp that arises in the maxillary antrum and prolapses into the nasal cavity where it expands backwards into the nasopharynx and occasionally into the oropharynx (Figures 48.19 and 48.20). It may mimic an angiofibroma from which it is distinguished by its avascularity and pale colour, and its site of origin on endoscopic examination and imaging. It requires complete removal via an endoscopic approach through the middle meatus or, occasionally, a Caldwell–Luc procedure.

Malignant

Nasopharyngeal carcinoma

Nasopharyngeal carcinomas are usually squamous cell carcinomas and have a very variable incidence. In most parts of the world, the tumour is rare with an annual incidence of one case per 100 000 population; however, among southern Chinese populations the rate is 30–50 cases per 100 000 population.

George Walter Caldwell, 1834–1918, otolaryngologist, who practised successively in New York, San Francisco and Los Angeles, USA, devised this operation for treating suppuration in the maxillary antrum in 1893.

Henri Luc, 1855–1925, otolaryngologist, Paris, France, described his operation in 1889.

Figure 48.18 Intraoperative photograph showing an incision in lateral rhinotomy.

Figure 48.19 Intraoral view showing a fleshy polyp hanging in the oropharynx.

Figure 48.20 Axial computed tomogram of an antrochoanal polyp (as seen in Figure 48.19), with opaque maxillary antrum and a mass in the nasal cavity and nasopharynx.

The aetiology of nasopharyngeal carcinoma is multifactorial. Genetic susceptibility, early infection by the Epstein–Barr virus and consumption of traditional diets, particularly salted fish, are known to contribute (Summary box 48.4).

Summary box 48.4

Aetiological factors in nasopharyngeal carcinoma

- Genetic, e.g. Cantonese
- Infective, e.g. Epstein–Barr virus
- Environmental, e.g. salted fish

The majority of tumours are undifferentiated with a characteristic morphology, comprising over 90 per cent of nasopharyngeal malignancy in endemic areas. Rare epithelial tumours are adenocarcinoma and adenoid cystic carcinoma. B- and T-cell lymphomas also occur in this region and should not be confused with the more common undifferentiated carcinoma. Nasopharyngeal carcinoma has a bimodal distribution with an increased incidence in teenagers and young adults and then again in the 50–60 age group.

Clinical features

Symptoms are closely related to the position of the tumour in the nasopharynx and the degree of distant spread if any. Early symptoms are often minimal and may be ignored by both patient and doctor. Approximately 50 per cent of patients will

present with a mass of malignant nodes in the neck, indicating an advanced tumour. This percentage is even higher in patients under 21 years of age. Fine-needle aspiration or a biopsy of a neck node showing undifferentiated carcinoma requires immediate thorough examination of the nasopharynx. In about 5 per cent of patients, the nasopharynx may look normal or minimally asymmetrical but contains submucosal nasopharyngeal carcinoma. A biopsy of the nasopharynx is essential if there is suspicion of nasopharyngeal malignancy. Nasal complaints occur in one-third of patients and aural symptoms of unilateral deafness as a consequence of Eustachian tube obstruction and secretory otitis media occur in approximately 20 per cent. Neurological complications with cranial nerve palsies as a result of disease in the skull base occur relatively late in the disease, but are a poor prognostic factor (Summary box 48.5).

Summary box 48.5

Nasopharyngeal carcinoma: main presenting complaints

Systemic

- Cervical lymphadenopathy

Local

- Unilateral serous otitis media, otalgia
- Nasal obstruction, bloody discharge, epistaxis
- Cranial nerve palsies, especially III–VI then IX–XII

Investigation is by direct inspection with a flexible or rigid nasendoscope and biopsy under topical or general anaesthesia. Serological investigation for Epstein–Barr virus-associated antigenic markers in combination with the clinical and histological examination is valuable for the early detection of disease. Highly sensitive assays for antiviral antibodies together with virus-associated serological markers are useful in early detection. Immunoglobulin (Ig)A antiviral capsid antigen antibody and early antigen antibody have been evaluated in mass surveys in southern China and have been found to be an excellent screening method for the early detection of nasopharyngeal carcinoma in high-risk groups.

Imaging

Imaging is essential for staging and to determine the extent of disease. The investigation of choice is MRI with gadolinium and fat suppression. This allows for assessment of brain parenchyma, cavernous sinus and the closely associated cranial foramina. CT or positron emission tomography (PET) CT of the head, neck and chest has a major role in planning radiotherapy and assessing the response to treatment, diagnosing recurrence and detecting complications.

Treatment

The primary treatment of nasopharyngeal carcinoma is external beam or intensity modulated radiotherapy as the majority of the tumours are radiosensitive undifferentiated squamous cell carcinomas. Elective bilateral external radiotherapy is given to the skull base and neck in all patients, even when no neck nodes are apparent. Chemotherapy in both the adjuvant and neoadjuvant setting remains controversial. Surgery is usually reserved for regional recurrence in the neck. For early disease, three-year disease-free survival rates of more than 75 per cent are common;

however, in advanced disease the results are less good, with three-year disease-free survival rates of 30–50 per cent.

OROPHARYNX

Acute tonsillitis

This common condition is characterised by a sore throat, fever, general malaise, dysphagia, enlarged upper cervical nodes and sometimes referred otalgia. Approximately half the cases are bacterial, the most common cause being a pyogenic group A streptococcus. The remainder are viral and a wide variety of viruses have been implicated, in particular infectious mononucleosis, which may be mistaken for bacterial tonsillitis.

On examination, the tonsils are swollen and erythematous, and yellow or white pustules may be seen on the palatine tonsils, hence the name 'follicular tonsillitis' (Figure 48.21). A throat swab should be taken at the time of examination as well as blood for Paul–Bunnell testing.

Treatment

Paracetamol or similar analgesia may be administered to relieve pain and gargles of glycerol–thymol are soothing. The condition is frequently sensitive to benzyl- or phenoxymethylpenicillin (penicillin V) and these are given until antibiotic sensitivities are established. Ampicillin is avoided as it may precipitate a rash in patients with infectious mononucleosis. Most cases resolve in a few days.

Quinsy

This is an abscess in the peritonsillar region that causes severe pain and trismus (Figure 48.22). The trismus caused by spasm induced in the pterygoid muscles may make examination difficult but may be overcome by instillation of local anaesthesia into the posterior nasal cavity (anaesthetising the sphenopalatine ganglion) and the oropharynx. Inspection reveals a diffuse swelling of the soft palate just superior to the involved tonsil, displacing the uvula medially. In more advanced cases, pus may be seen pointing underneath the thin mucosa.

Treatment

In the early stages, intravenous broad-spectrum antibiotics may produce resolution. However, if there is frank abscess formation, incision and drainage of the pus can be carried out under

Figure 48.21 Acute follicular tonsillitis.

Figure 48.22 Quinsy (peritonsillar abscess).

local anaesthesia. A small scalpel is best modified by winding a strip of adhesive tape around the blade so that only 1 cm of the blade projects. In teenagers and young adults, the patient sits upright and an incision is made approximately midway between the base of the uvula and the third upper molar tooth (Figure 48.23). This may produce immediate release of pus, but, if not, a dressing forceps is pushed firmly through the incision and, on opening, pus may then be encountered. In small children, general anaesthesia is required.

Chronic tonsillitis

Chronic tonsillitis usually results from repeated attacks of acute tonsillitis in which the tonsils become progressively damaged and provide a reservoir for infective organisms.

Tonsillectomy

Recurrent acute tonsillitis is the most common relative indication for tonsillectomy in children and adolescents, although it is important that these attacks are well documented, frequent and do not simply constitute a minor viral sore throat. Chronic tonsillitis more frequently affects young adults, in whom it is important to establish that chronic mouth breathing secondary to nasal obstruction is not the main problem rather than the tonsils themselves. Absolute indications for tonsillectomy are when the size of the tonsils is contributing to airway obstruction or a malignancy of the tonsils is suspected (Table 48.1).

Figure 48.23 Site of incision in peritonsillar abscess.

Table 48.1 Indications for tonsillectomy.

Absolute	Sleep apnoea, chronic respiratory tract obstruction, cor pulmonale Suspected tonsillar malignancy
Relative	Documented recurrent acute tonsillitis Chronic tonsillitis Peritonsillar abscess (quinsy) Tonsillar asymmetry Tonsillitis resulting in febrile convulsions Diphtheria carriers Systemic disease caused by β -haemolytic <i>Streptococcus</i> (nephritis, rheumatic fever)

Ideally, the procedure should be undertaken when the tonsils are not acutely infected, and it is important to discuss factors that may increase the tendency to bleed. Blood transfusion is rarely required, but it is normal practice to type and screen blood for cross-match in children under 15 kg in weight.

Dissection tonsillectomy is carried out under general anaesthesia. The mucosa of the anterior faucial pillar is incised and the tonsil capsule identified. Using blunt dissection, the tonsil is separated from its bed until only a small inferior pedicle is left (Figure 48.24). It is then separated from the lingual tonsil. A tonsil swab is placed in the tonsillar bed and pressure applied for some minutes, following which bleeding points may be controlled by ligature or by bipolar diathermy.

Following surgery, the patient is kept under close observation for any systemic or local evidence of bleeding, with regular pulse and blood pressure measurements and observation to see whether the patient is swallowing excessively (Figure 48.25). Postoperatively, patients are encouraged to eat normally. Paracetamol is preferred to non-steroidal analgesics. Patients are allowed home on the same or following day and are warned that they may experience otalgia as a result of referred pain from the glossopharyngeal nerve and that secondary haemorrhage may occur up to 10 days following the surgery.

Figure 48.24 Removal of the tonsils.

Haemorrhage is the most common complication in the immediate postoperative period. Local pressure may help in mild cases, but reactionary haemorrhage usually requires return to theatre for definitive treatment, particularly in younger patients. Under general anaesthesia, it may be possible to identify a bleeding spot, but often a more generalised ooze is observed and suturing of the tonsil bed combined with the application of Surgicel and bipolar diathermy is often more successful than attempted placement of ligatures.

Late haemorrhage is generally secondary to infection and patients should be commenced on intravenous antibiotics with aerobic and anaerobic cover. Significant or persistent bleeding may require a further general anaesthetic and undersewing of the surgical bed, which by this time will often be covered with slough and granulation tissue. Postoperative tonsillar haemorrhage is still a serious and life-threatening complication and should not be underestimated, particularly in the younger patient (Summary box 48.6).

Summary box 48.6

Complications of tonsillectomy

- Haemorrhage (immediate or late)
- Infection
- Pain/otalgia
- Postoperative airway obstruction
- Velopharyngeal insufficiency

Parapharyngeal abscess

Parapharyngeal abscess may be confused with a peritonsillar abscess, but the maximal swelling is **behind** the posterior faucial pillar and there may be little oedema of the soft palate. The patient is usually a young child and there may be a severe general malaise. In early cases, admission to hospital and the institution of fluid replacements coupled with intravenous antibiotics may produce resolution. In advanced cases, drainage and intravenous antibiotics are required. With an obvious abscess pointing into the oropharynx, drainage may be carried out with a blunt instrument or the glove finger, but general anaesthesia is frequently required and the expertise of a senior anaesthetist, good illumination and good suction are absolutely essential. A large parapharyngeal abscess may compromise both the airway and swallowing.

Figure 48.25 Positioning of the patient after tonsillectomy.

Acute retropharyngeal abscess

This is the result of suppurative of the retropharyngeal lymph nodes and, again, is most commonly seen in children, with most cases occurring under one year of age. It is associated with infection of the tonsils, nasopharynx or oropharynx, and is frequently accompanied by severe general malaise, neck rigidity, dysphagia, drooling, a croupy cough, an altered cry and marked dyspnoea.

Dyspnoea may be the prominent symptom and may also be accompanied by febrile convulsions and vomiting. These children should always be carefully examined. Inspection of the posterior wall of the pharynx may show gross swelling and an abscess pointing beneath the thinned mucosa.

In countries where diphtheria still occurs, an acute retropharyngeal abscess may be confused with this, but the presence of the greyish-green membrane aids differentiation. Occasionally, a foreign body, most commonly a fish bone which has perforated the posterior pharyngeal mucosa, will give rise to a retropharyngeal abscess in older children and young adults. Intravenous antibiotics are commenced immediately, but surgical drainage of the abscess is often necessary. It requires experienced anaesthesia because, on induction, care must be taken to avoid rupturing the abscess. The airway is protected by placing the child in a head-down position while a pair of dressing forceps guided by the finger may be thrust into an obvious abscess in the posterior wall and the contents evacuated. On other occasions, an approach anterior and medial to the carotid sheath via a cervical incision may be required.

Chronic retropharyngeal abscess

This condition is now rare and is most commonly the result of an extension of tuberculosis of the cervical spine, which has spread through the anterior longitudinal ligament to reach the retropharyngeal space. In addition to the retropharyngeal swelling seen intraorally, there may be fullness behind the sternocleidomastoid muscle on one side. In contrast to an acute retropharyngeal abscess, this condition occurs almost solely in adults. Radiology usually shows evidence of bone destruction and loss of the normal curvature of the cervical spine. The spine may be quite unstable and undue manipulation may precipitate a neurological event.

A chronic retropharyngeal abscess must not be opened into the mouth, as such a procedure may lead to secondary infection. Drainage of the abscess may not be necessary if suitable treatment of the underlying tuberculosis disease is instituted. If it is necessary, drainage should be carried out through a cervical incision anterior to the sternocleidomastoid muscle with an approach anterior and medial to the carotid sheath to enter the retropharyngeal space. The cavity is opened and suctioned dry after taking biopsy material. Occasionally, surgery is required to decompress the spinal cord if there is a progressive neurological deficit.

Glandular fever (infectious mononucleosis)

This systemic condition is usually caused by the Epstein-Barr virus, but similar features can be caused by cytomegalovirus or toxoplasmosis. The tonsils are typically erythematous with a creamy grey exudate and appear almost confluent, usually symmetrical in contrast to a quinsy. In addition to the discomfort

and dysphagia, patients may drool saliva and have respiratory difficulty, particularly on inspiration. They commonly have a high temperature and gross general malaise with other notable cervical or generalised lymphadenopathy. Occasionally, an enlarged spleen or liver may be detected. The condition is most frequent in teenagers and young adults. The diagnosis can be confirmed by serological testing showing a positive Paul-Bunnell test, an absolute and relative lymphocytosis, and the presence of atypical monocytes in the peripheral blood.

Treatment

Analgesia and maintenance of fluid intake are important. A small number of patients require admission to hospital if the airway is compromised and a short course of steroids may be helpful. Antibiotics are of little value and ampicillin is contraindicated because of the frequent appearance of a widespread skin rash. Rarely if the airway is severely compromised, an unhurried elective tracheostomy under local anaesthesia is safer and less traumatic than an emergency intubation. Emergency tonsillectomy is contraindicated because of the generalised pharyngeal oedema and compromised airway.

Human immunodeficiency virus

Acquired immune deficiency syndrome (AIDS) can affect the ear, nose and throat (ENT) system at any point during the disease. The initial seroconversion may present with the symptoms of glandular fever, which is followed by an asymptomatic period of variable length. In the pre-AIDS period, before the full-blown symptoms of the AIDS-related complex, many patients have minor upper respiratory tract symptoms that are often overlooked, such as otitis externa, rhinosinusitis and a non-specific pharyngitis. As the patient moves into the full-blown AIDS-related complex, a persistent, generalised lymphadenopathy is frequently found affecting the cervical nodes, which is usually due to follicular hyperplasia. However, patients may also develop tumours such as Kaposi's sarcoma, sometimes seen in the oral cavity, and high-grade malignant B-cell lymphoma affecting the cervical lymph nodes and nasopharynx. In addition, multiple ulcers may be found in the oral cavity or pharynx associated with herpes infection. Severe candida may affect the oral cavity, pharynx, oesophagus or even larynx, and a hairy leukoplakia may affect the tongue (Figure 48.26).

The globus syndrome

A wide variety of patients experience the feeling of a lump in the throat (from the Latin *globus* = lump). The symptom most commonly affects adults between 30 and 60 years of age. This feeling is not true dysphagia as there is no difficulty in swallowing. Most patients notice the symptom more if they swallow their own saliva, i.e. a forced, dry swallow, rather than when they eat or drink.

The aetiology of this common symptom is unknown, but some patients may have gastro-oesophageal reflux or spasm of their cricopharyngeal muscle.

The original name of 'globus hystericus' is unhelpful and although these patients may be anxious and at times introverted, they nonetheless require full examination to exclude local disease. Radiological and endoscopic investigation may be necessary to exclude an underlying cause.

Figure 48.26 Intraoral view showing hairy tongue in a human immunodeficiency virus-positive patient.

Pharyngeal pouch

A pharyngeal pouch is a protrusion of mucosa through Killian's dehiscence, a weak area of the posterior pharyngeal wall between the oblique fibres of the thyropharyngeus and the transverse fibres of cricopharyngeus at the lower end of the inferior constrictor muscle (Figure 48.27). These fibres, along with the circular fibres of the upper oesophagus, form the physiological upper oesophageal sphincter mechanism. Why the pouch forms is not yet clear, even with modern videofluoroscopic and manometric studies. Many patients with pharyngeal pouches have been demonstrated to have normal relaxation of the upper oesophageal sphincter mechanism in relation to swallowing, but others have been shown to have incomplete pharyngeal relaxation, early cricopharyngeal contraction and abnormalities of the pharyngeal contraction wave.

Clinical features

Patients suffering from this condition are commonly more than 60 years of age and it is more common in men than women. As the diverticulum enlarges, patients may experience regurgitation of undigested food, sometimes hours after a meal, particularly if they are bending down or turning over in bed at night. They sometimes wake at night with a feeling of tightness in the throat and a fit of coughing. Occasionally, they may present with recurrent, unexplained chest infections as a result of aspiration of the contents of the pouch. As the pouch increases in size, the patients may notice gurgling noises from the neck on

Figure 48.27 A pharyngeal pouch.

swallowing and the pouch may become large enough to form a visible swelling in the neck.

Radiological examination

A thin emulsion of barium is given to the patient as a barium swallow (Figure 48.28) or, ideally, as part of a videofluoroscopic swallowing study. Care should be exercised in patients who cough on swallowing, indicating they may have aspiration. A small volume of barium is sufficient to outline the pharynx, pouch and upper oesophagus. The videofluoroscopic study gives additional information about the pharyngeal contraction waves and the performance of the upper oesophageal sphincter.

Treatment

Surgery is indicated when the pouch is associated with progressive symptoms and particularly when a prominent cricopharyngeal bar of muscle associated with abnormality of the upper oesophageal sphincter mechanism causes considerable dysphagia. In elderly patients, a decision to operate may be influenced by their general condition. Preoperative chest physiotherapy and attention to the respiratory, cardiovascular and nutritional aspects of the patient are important. Perioperative antibiotics are recommended.

The preferred surgical technique is with endoscopic stapling of the diverticular wall. A double-bladed rigid endoscope is passed, with one blade in the diverticulum and one blade positioned in the oesophagus. An endoscopic linear stapler is then passed. One jaw of the stapler is placed in the oesophagus, the other in the pouch. The stapler is fired dividing the wall separating the two. The process should be repeated until the bottom of the pouch is reached. This has the effect of opening the pouch, incorporating it as part of the oesophageal wall and dividing the cricopharyngeus muscle. If the patient is symptom free after the procedure they may start graded peroral intake and early discharge.

In the classic external operation, the opening to the pouch is first identified using a pharyngoscope and a nasogastric tube placed into the oesophageal lumen for postoperative nutrition.

Figure 48.28 Barium swallow showing a pharyngeal pouch.

This initial endoscopy is often difficult because the normal oesophageal opening is small compared with the lumen of the pouch, but it may be better visualised using a Dohlmann's rigid endoscope. The pouch may be packed with ribbon gauze soaked in proflavin solution to further aid identification of its neck.

A lower neck incision along the anterior border of the left sternocleidomastoid muscle, or a transverse crease incision, is used and the muscle and carotid sheath are retracted laterally and the trachea and larynx medially. The pouch is found medially behind the lower pharynx and is carefully isolated and dissected back to its origin at Killian's dehiscence. It is then excised and the pharynx closed in two layers or, if it is small, the pouch may be invaginated into the pharyngeal lumen before closing the muscle layers. In all cases, a myotomy dividing the fibres of the cricopharyngeus muscle and the upper oesophageal circular muscle fibres must be performed. The wound is usually closed with drainage and the patient fed through a nasogastric tube for 3–7 days.

The average operating time with an endoscopic procedure is 20–30 minutes compared with 60–90 minutes with an external procedure. Inpatient stay is also decreased for patients undergoing an endoscopic procedure. The endoscopic technique is associated with a high symptomatic success rate and a low morbidity which is particularly important in the elderly.

Complications

The classic operation has been associated with wound infection, mediastinitis, pharyngeal fistula formation, recurrent laryngeal nerve palsy and stenosis of the upper oesophagus. Endoscopic division is associated with the same risks but at lower rates. The recurrence rates between the two procedures appear to be equal; longer-term follow up will establish this. Endoscopic stapling will also allow for safe reoperation if necessary.

Other approaches

Variations have been tried which include simply hitching up the pouch into a superior position without excising it, thus allowing the fundus and body to empty continuously into the oesophagus. This is unsatisfactory with larger pouches, and upper oesophageal myotomy is still required.

Carbon dioxide or argon laser division of the diverticular wall via a special pharyngoscope may also be used. These techniques are associated with a higher recurrence rate than both endoscopic and open repair.

Sideropenic dysphagia

Prolonged iron deficiency anaemia may lead to dysphagia, particularly in middle-aged women. In addition, they may have koilonychia, cheilosis, angular stomatitis together with lassitude and poor exercise tolerance. The dysphagia is caused by a postcricoid or upper oesophageal web and these patients have a higher incidence of postcricoid malignancy. The syndrome is associated with the names of Plummer and Vinson, Paterson and Brown Kelly.

TUMOURS OF THE OROPHARYNX

Benign

Benign tumours of the oropharynx are rare, papillomas being the most common. These are usually incidental findings and are rarely of any importance.

Malignant

The most important epithelial tumour is squamous cell carcinoma, which constitutes approximately 90 per cent of all epithelial tumours in the upper aerodigestive tract (Figures 48.29 and 48.30). In the oropharynx, the proportion is less (70 per cent) because of the higher incidence of lymphoma (25 per cent) and salivary gland tumours (5 per cent).

Aetiology

Squamous carcinomas of the oropharynx are strongly associated with cigarette smoking and consumption of alcohol. In countries where the consumption of tobacco and alcohol are associated with poor oral hygiene, these malignancies assume major importance. Because of the rich lymphatic drainage of the oropharynx, cervical node metastases are common. They may be the only presenting feature with an apparent occult primary

Figure 48.29 Squamous cell carcinoma of the right tonsil.

Figure 48.30 Squamous cell carcinoma of the soft palate.

Henry Stanley Plummer, 1874–1937, physician, The Mayo Clinic, Rochester, MN, USA, described this syndrome in 1912.
 Porter Paisley Vinson, 1890–1959, physician, The Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.
 Donald Rose Paterson, 1863–1939, surgeon, Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, UK.
 Adam Brown Kelly, 1865–1941, surgeon, Ear, Nose and Throat Department, The Royal Victoria Infirmary, Glasgow, UK.
 Vinson, Paterson and Kelly all described this syndrome independently in 1919.

tumour often being unsuspected and missed in the tonsil or tongue base.

Treatment

Treatment varies with facilities around the world, but early tumours may be cured by chemoradiotherapy, laser excision or more conventional excision. Recurrent disease following radiotherapy is usually managed surgically and repair of the oropharynx may require regionally based myocutaneous flaps or free flaps with microvascular anastomosis. Neck dissection is required in a large proportion of cases of advanced disease. Postoperative dysphagia with aspiration as a result of interference in the complex neuromuscular control of the second phase of swallowing is a particular problem in these patients. This type of surgery is best carried out in a major centre undertaking this work on a regular basis.

Lymphoma of the head and neck

Lymphomas of the head and neck may arise in nodal or extra-nodal sites and both Hodgkin's disease and non-Hodgkin's lymphoma commonly present as lymph node enlargement in the neck. Hodgkin's disease is rare in the oropharynx, but non-Hodgkin's lymphoma accounts for 15–20 per cent of tumours at this site in some countries. Most are of the B-cell type and have features in common with other MALT tumours. Further evaluation with CT scanning of the thorax and abdomen, and bone marrow evaluation are essential. Fine-needle aspiration cytology of neck lymph nodes is now mandatory and flow cytometry of the aspirates have aided in diagnosis and classification of lymphomas.

Radiotherapy is the treatment of choice for localised non-Hodgkin's lymphoma and may give control rates as high as 75 per cent at five years. For disseminated non-Hodgkin's lymphoma, systemic chemotherapy is preferred.

TUMOURS OF THE HYPOPHARYNX

Benign

Benign tumours of the hypopharynx are very rare, the most common being the fibroma and the leiomyoma. They show a smooth, constant mass lying in the lumen of the hypopharynx or oesophagus.

Malignant

Malignant tumours of the hypopharynx are almost exclusively squamous cell carcinomas with a predominance of moderate and poor differentiation. The tumours are usually classified according to their probable anatomical site of origin from the pyriform fossa, post-cricoid region or posterior pharyngeal wall. Marked differences in the incidence of these tumours occur globally because of factors such as iron-deficiency anaemia (see above under Sideropenic dysphagia). They may be associated with marked submucosal spread of 10 mm or more, which further complicates evaluation. Tumours arising from the pyriform fossa and posterior pharyngeal wall may spread to upper or lower cervical nodes. Tumours arising in the post-cricoid area typically metastasise to paratracheal and paraoesophageal nodes, which may not be palpable. As with oropharyngeal tumours, alcohol and tobacco are two principal carcinogens. Post-cricoid carcinoma, though rare, is more common in women than men.

The diagnosis of hypopharyngeal carcinoma should be considered in all patients presenting with dysphagia, hoarseness or referred otalgia, particularly if they have a history of iron deficiency anaemia, smoking or significant alcohol consumption.

Fibreoptic endoscopic examination in clinic may show only subtle signs, such as oedema or pooling of saliva unilaterally in the pyriform fossa. Note should also be made that this region is not well seen on flexible gastroscopy. Preferred investigation is with direct rigid pharyngoscopy and oesophagoscopy with biopsy under a general anaesthetic. All regions of the neck must be assessed in a systematic manner. Fine-needle aspirate is advocated for suspicious nodes.

Radiological examination

A suspected primary requires a neck and staging CT and/or MRI of the neck.

Treatment

Squamous carcinoma of the hypopharynx commonly presents late and carries a poor prognosis. Early lesions may be treated with chemoradiotherapy or transoral endoscopic carbon dioxide laser resection. Major open excisional surgery is generally used for recurrence after radiotherapy or as primary excision in advanced disease. Total pharyngolaryngectomy is commonly required (Figure 48.31) and for lesions extending into the upper oesophagus, oesophagectomy with gastric pull-up or free flap reconstruction may be needed. Myocutaneous flaps, transposed jejunum or stomach are used to reconstruct the pharynx. Swallowing and voice rehabilitation are necessary to support patients after this major surgery if they are to adjust and maintain some quality of life (Summary box 48.7).

Figure 48.31 Total pharyngolaryngectomy specimen showing hypopharyngeal carcinoma (hypopharynx opened from posterior).

Summary box 48.7**Tumours of the hypopharynx**

- Variable symptoms – discomfort, pain, dysphagia, hoarseness
- Awareness increased by history of smoking and alcohol
- Expert examination with nasendoscopy
- Referral to expert for detailed assessment and treatment – radiotherapy, laser or extensive surgery

DISEASES OF THE LARYNX**Emergencies****Stridor**

Stridor means noisy breathing. It may be inspiratory or expiratory, or occurring in both phases of respiration. Inspiratory stridor is usually due to an obstruction at or above the vocal folds and is most commonly the result of an inhaled foreign body or acute infections such as epiglottitis. Expiratory stridor is usually from the lower respiratory tract and gives rise to a prolonged expiratory wheeze. It is most commonly associated with acute asthma or acute infective tracheobronchitis. Biphasic stridor is usually due to obstruction or disease of the tracheobronchial airway and distal lungs (Summary box 48.8).

Summary box 48.8**Stridor****Inspiratory**

- Foreign body or epiglottitis

Expiratory

- Acute asthma or infective tracheobronchitis

Biphasic

- Obstruction, disease of tracheobronchial airway or distal lungs

Stridor in children

Infants and children presenting with stridor need careful assessment with a full history and examination as appropriate. If, on presentation, a child is cyanosed and severely unwell, the airway must be secured as soon as possible, but a brief history with important pointers can often be obtained from the parents.

History

In infants in the first year of life, it is important to establish if the stridor is associated with particular activities such as swallowing, crying or movement. These may suggest congenital laryngomalacia or subglottic stenosis. If the stridor is exacerbated by feeding, particularly in the first 4 weeks of life, this suggests a vascular ring or tracheo-oesophageal fistula. If the cry is weak or abnormal, this suggests a vocal fold palsy. If the problem only occurs in association with an upper respiratory tract infection and, in particular, is biphasic, this would suggest congenital subglottic stenosis. In a young child, inspiratory stridor and drooling suggest acute epiglottitis, whereas biphasic

stridor without drooling suggests laryngotracheobronchitis or croup (Summary box 48.9).

Summary box 48.9**Acute paediatric stridor****Congenital**

- Laryngomalacia
- Laryngeal web
- Subglottic stenosis

Acquired

- Inflammatory
 - Angioneurotic oedema
- Traumatic
 - Impacted foreign body, laryngeal fracture
- Infective
 - Epiglottitis, laryngotracheobronchitis
- Neurological
 - Vocal fold palsy
- Neoplasia
 - Benign laryngeal papillomatosis

Examination

It is important when possible to observe the child carefully at rest. Once a baby starts to cry, it may be impossible to study its resting respiratory pattern for some time. Ask the mother, not a nurse or a colleague, to move a baby or young child into different positions, such as face down and supine, and watch for changes in respiratory pattern and level of distress. Observe any drooling and, with neonates and infants, always try to watch the child being fed, listening to the trachea and chest with a stethoscope if possible. Always examine the whole child, looking for any evidence of congenital abnormalities before attempting any examination of the throat.

If a child is stridulous and drooling and sitting upright in its mother's arms or a chair, do not attempt to lie it down and do not attempt to look inside the mouth. These manoeuvres are potentially life-threatening as the child may aspirate a large quantity of thick saliva contained within the oral cavity. The child does not wish to attempt swallowing in the case of a retropharyngeal abscess, parapharyngeal abscess or acute epiglottitis as these conditions are so painful. It is particularly important in acute epiglottitis as the aspiration of thick saliva may be associated with further laryngeal spasm and a respiratory arrest. Restlessness, increasing tachycardia and cyanosis are important signs of hypoxia. If the child is not distressed and drooling, and not markedly stridulous, he/she may be cooperative enough that it is possible to look inside the mouth and check the palate, tongue and oropharynx. In stridulous children, particularly neonates and infants, a transcutaneous oximeter is invaluable. A resuscitation trolley with the necessary equipment for emergency intubation or tracheostomy should be close at hand if at all possible before commencing examination.

Investigation

Plain lateral radiographs of the neck and a chest radiograph can be obtained but only if the child's condition permits. If a child is severely stridulous, they should not be sent to a radiography department without access to medical staff or resuscitation equipment.

Examination under anaesthesia is essential in all children whose diagnosis remains in doubt. This requires a high level of skill and appropriate rigid laryngoscopes, bronchoscopes, endoscopic Hopkins' rods and an operating microscope should be made available if possible. Equipment should be available at all times to undertake an urgent tracheostomy to establish or maintain an airway.

Acute epiglottitis

In children, acute epiglottitis is of rapid onset. It tends to occur in children of two years of age and over. Stridor is usually associated with drooling of saliva. The condition is caused by *Haemophilus influenzae* infection, which initially causes a severe pharyngitis at the junction of the oro- and hypopharynx before producing inflammation and oedema of the laryngeal inlet. As it progresses, it involves the whole of the supraglottic larynx, with severe oedema of the aryepiglottic folds and epiglottitis being the most notable component, hence the commonly used term 'acute epiglottitis'.

These children frequently require intensive management with emergency intubation or tracheostomy followed by oxygenation, humidification, continuous oximetry and antibiotics such as ampicillin or chloramphenicol. There may be associated septicaemia so blood cultures should be obtained. Attempted examination with a spatula into the mouth may precipitate a respiratory arrest and should be avoided. The incidence of acute epiglottitis has plummeted where *Haemophilus influenzae* vaccination programmes have occurred.

Laryngotracheobronchitis (croup)

Croup is usually of slower onset than acute epiglottitis and occurs most commonly in children under two years of age. It is usually viral in origin and the cases often occur in clusters. The children have biphasic stridor, and are often hoarse with a typical barking cough. Airway intervention is required less often, but admission to hospital with oxygenation and humidification, coupled with antibiotics, may be necessary if there are signs of secondary infection.

Foreign bodies

Both children and adults may inhale foreign bodies. Young children will attempt to swallow a wide variety of objects, but coins, beads and parts of toys are particularly common. In adults, the aspiration is usually food, particularly inadequately chewed bones and meat. This is more common in elderly edentulous adults. Occasionally, portions of dentures may be inhaled, particularly in association with road traffic accidents.

Clinical features

The history is paramount and a history of foreign body ingestion or inhalation in a child, even though the pain, dysphagia, coughing, etc. may have settled, should always be taken seriously.

Adults usually have a clear recall, which facilitates diagnosis. Fish bones may lodge in the tonsils or base of tongue with minimal symptoms, but small fish bones may give rise to para- and retropharyngeal abscess formation.

Examination

Examination may be prevented by trismus, pain and anxiety, but the presence of a foreign body may be suspected by a salivary

pool within the pyriform fossa or adjacent oedema and erythema of the pharyngolaryngeal mucosa.

Radiology

Radiology may be helpful but is not critical. Fish bones are often invisible on plain radiographs and a normal plain radiograph does not exclude a foreign body within the pharynx, larynx, oesophagus or lungs.

Specialised studies may help in cases of doubt, using a CT scan or a gastrografin swallow in the case of a suspected oesophageal foreign body.

Treatment

In the case of an inhaled foreign body causing severe stridor in a neonate or infant, it may be removed either by hooking it from the pharynx with a finger or by inverting the child carefully by the ankles and slapping his/her back. In a larger child, it may be more appropriate to bend them over your knee with their head hanging down and again strike them firmly between the shoulders. In the case of adults, an impacted laryngeal foreign body may be coughed out using a Heimlich manoeuvre. This involves standing behind the patient, clasping the arms around the lower thorax, such that the knuckles of the clasped hands come into contact with the patient's xiphisternum, and then a brief, firm compression of the lower thorax may aid instant expiration of the foreign body. If none of these immediate emergency measures removes the foreign body and the patient is cyanosed and severely stridulous, an immediate cricothyroidotomy or tracheostomy may be necessary. In less urgent cases, and when a foreign body is strongly suspected, endoscopy under general anaesthesia may be indicated.

Other causes of acute pharyngolaryngeal oedema

Angioneurotic oedema, radiotherapy, laryngeal trauma associated with road traffic accidents, corrosives, scalds and smoke ingestion may all cause significant pharyngolaryngeal oedema, in addition to the acute infective conditions mentioned elsewhere. Hoarseness is the predominant symptom along with dysphagia prior to the increase in dyspnoea. If flexible laryngoscopic examination is possible, marked oedema of the supraglottis and pharynx can be seen. Humidified oxygen, adrenaline nebulisers, systemic antihistamines and steroids may be valuable. Morphine should not be given as it may cause respiratory depression and respiratory arrest. If the dyspnoea progresses, intubation or tracheostomy will be necessary.

TRACHEOSTOMY AND OTHER EMERGENCY AIRWAY MEASURES

This procedure relieves airway obstruction or protects the airway by fashioning a direct entrance into the trachea through the skin of the neck. Tracheostomy may be carried out as an emergency when the patient is *in extremis* and the larynx cannot be intubated, but it is not always an easy procedure, particularly in an obese patient. An easier alternative for the inexperienced is insertion of a large intravenous cannula or a small tube into the cricothyroid membrane, which lies in the midline immediately below the thyroid cartilage. Emergency intubation is a further option when the laryngotracheal airway is not obstructed and tracheostomy may be performed thereafter. **The time to do a tracheostomy is when you first think it may be necessary.**

If time allows, the following should be undertaken:

- inspection and palpation of the neck to assess the laryngotracheal anatomy in the individual patient;
- indirect or direct laryngoscopy;
- assessment of pulmonary function.

Whenever possible, the procedure should be adequately explained to the patient beforehand, with particular emphasis on the inability to speak immediately following the operation. Ample reassurance is required that they will not have 'lost' their voice permanently. The indications for tracheostomy are shown in Summary box 48.10.

Summary box 48.10

Indications for tracheostomy

Acute upper airway obstruction

- For example, an inhaled foreign body, a large pharyngolaryngeal tumour, or acute pharyngolaryngeal infections in children

Potential upper airway obstruction

- For example, after major surgery involving the oral cavity, pharynx, larynx or neck

Protection of the lower airway

- For example, protection against aspiration of saliva in unconscious patients as a consequence of head injuries, faciomaxillary injuries, comas, bulbar poliomyelitis or tetanus

Patients requiring prolonged artificial respiration

- Best performed within 10 days of ventilation

Emergency tracheostomy

If a skilled anaesthetist is unavailable, local anaesthesia is employed, but in desperate cases when the patient is unconscious, none is required. In patients who have suffered severe head and neck trauma and who may have an unstable cervical spine fracture, cricothyroidotomy may be more suitable. If it is possible, the patient should be laid supine with padding placed under the shoulders and the extended neck kept as steady as possible in the midline. This aids palpation of the thyroid and cricoid cartilage between the thumb and index finger of the free hand. The movements of the fingers of the free hand are important in this technique. The operation is more difficult in small children and thick-necked adults as the landmarks are difficult to palpate (Figures 48.32 and 48.33).

A vertical midline incision is made from the inferior aspect of the thyroid cartilage to the suprasternal notch and continued down between the infrahyoid muscles. There may be heavy bleeding from the wound at this point, particularly if the neck is congested as a result of the patient's efforts to breathe around an acute upper airway obstruction. No steps should be taken to control this haemorrhage, although an assistant and suction are valuable. The operator should feel carefully for the cricoid cartilage using the index finger of the free hand while retracting the skin edges by pressure applied by the thumb and middle finger. If the situation is one of extreme urgency, a further vertical incision straight into the trachea at the level of the second, third and fourth ring should be made immediately without regard to the presence of the thyroid isthmus. The knife blade is rotated

through 90°, thus opening the trachea. At this point, the patient may cough violently as blood enters the airway. The operator should be aware of this possibility and avoid losing the position of the scalpel in the open trachea. Any form of available tube should be inserted into the trachea as soon as possible and blood and secretion sucked out. Once an airway has been established, haemostasis is then secured. With the emergency under control, the tracheostomy should be refashioned as soon as possible.

Should additional equipment and more time be available once the cricoid cartilage has been identified, blunt finger dissection inferiorly can be used to mobilise the thyroid isthmus, which should be divided between haemostats, clearing the trachea before making a vertical incision through the second to the fourth rings. A tracheal dilator is inserted through the tracheal incision and the edges of the tracheal wound are separated gently. In cases of suspected human immunodeficiency virus (HIV) infection or diphtheria, the surgeon places a swab over the wound so that the violent expiratory efforts which may follow do not contaminate the operator(s) with infected mucus and blood. When respiratory efforts have become less violent, a tracheostomy tube is inserted into the trachea and the dilator removed. It is important that the surgeon keeps a finger on the tube while the assistant ties the attached tapes around the patient's neck. Return the neck to a neutral position before tying the tapes firmly.

Elective tracheostomy

The advantage of an elective surgical procedure is that there is complete airway control at all times, unhurried dissection and careful placement of an appropriate tube. Close cooperation between the surgeon, anaesthetist and scrub nurse is essential,

Figure 48.32 The position of skin incision in an emergency tracheostomy.

Figure 48.33 An incision in the trachea in an emergency tracheostomy.

and attention to detail will markedly reduce possible complications and morbidity from the procedure.

Following induction of general anaesthesia and endotracheal intubation, the patient is positioned with a combination of head extension and placement of an appropriate sandbag under the shoulders (Figure 48.34). There should be no rotation of the head. Children's heads should not be overextended as it is possible to enter the trachea in the fifth and sixth rings in these circumstances. Insertion of a bronchoscope in the trachea may help when performing tracheostomy in young children. A transverse incision may be used in the elective situation (Figure 48.35). The tracheal isthmus is divided carefully and oversewn and tension sutures placed either side of the tracheal fenestration in children (Figure 48.36). A Bjork flap may be used in adults (Figures 48.37 and 48.38).

The advantages of the Bjork method outweigh the potential disadvantages and it is useful for those surgeons who undertake occasional tracheostomy or when the level of skill and experience of the nursing staff is limited. It is generally avoided in experienced hands. Performed correctly, it is safe and allows reintroduction of a displaced tube with the minimum of difficulty.

The inferiorly based flap is begun at its apex with an incision on the superior aspects of the second ring and extends down either side through the second and third rings. The tip of the

Figure 48.34 Position of the patient for elective tracheostomy.

Figure 48.35 Position of a skin incision in an elective tracheostomy.

flap should be stitched to the inferior edge of the transverse skin incision using horizontal mattress sutures through the structure of the second ring. These sutures should be generous enough so that they will not cut out. The first tracheal ring should not be violated in any circumstances.

In a paediatric patient who requires a tracheostomy, failure to remain in the midline may result in pneumothorax, as pleural spaces extend into the root of the neck laterally. Prior to incision of the trachea vertical stay sutures are placed lateral to the midline through the tracheal rings and left in place. A vertical incision is made between the second and third tracheal rings. No tracheal tissue is removed. These can provide traction for the trachea and allow for rapid tracheostomy tube reinsertion if accidental decannulation occurs prior to the establishment of

Figure 48.36 Tracheal fenestration in an elective tracheostomy.

Figure 48.37 Bjork flap.

Figure 48.38 Fenestration in a Bjork flap.

the tract. Some surgeons will suture skin flaps to the trachea for additional safety.

Percutaneous tracheostomy

In many countries, tracheostomy may be performed percutaneously with bronchoscopic assistance. A transverse incision is made between the first and second tracheal rings, and blunt dissection of the midline is then performed. A 22-gauge needle is inserted between the second and third tracheal rings. When air

is aspirated into the syringe, the guidewire is introduced. After the guidewire is protected, dilators are introduced. All dilators are inserted in a sequential manner from small to large diameter. The tracheostomy tube is then introduced along the dilator and guidewire. The guidewire and dilator are removed, the cuff of the tracheostomy tube is inflated, and the breathing circuit is connected. The endotracheal tube can then be removed.

Patients must have appropriate anatomy and no limitation of neck movement. If any doubt arises as to the suitability of a patient for percutaneous tracheostomy a surgical approach should be adopted. Percutaneous tracheostomy is rarely performed in children.

Tracheostomy tubes

These are basically made of two materials: silver or plastic. Both materials have been used to make tubes of various sizes with varying curves, angles, cuffs, inner tubes and speaking valves (Figures 48.39 and 48.40). A cuffed tube is used initially, which may be changed after 3–4 days to a non-cuffed plastic or silver tube. The pressure within the tube cuff should be carefully monitored and should be low enough so as not to occlude circulation in the mucosal capillaries. When in position, the tube should be retained by double tapes passed around the patient's neck with a reef knot on either side. It is important that the patient's head is flexed when the tapes are tied, otherwise they may become slack when the patient is moved from the position of extension, thereby resulting in a possible displacement of the tube if the patient coughs. Alternatively, the flanges of the plastic tube may be stitched directly to the underlying neck skin.

All forms of tracheostomy and cricothyroidotomy bypass the upper airway and have the following advantages:

- The anatomical dead space is reduced by approximately 50 per cent.
- The work of breathing is reduced.
- Alveolar ventilation is increased.
- The level of sedation needed for patient comfort is decreased and, unlike endotracheal intubation, the patient may be able to talk and eat with a tube in place.

Figure 48.39 Silver tracheostomy tube. From above: introducer, outer tube and inner tube.

Figure 48.40 Modern plastic tracheostomy tube with introducer, low-pressure cuff and inner canula.

However, there are several disadvantages:

- Loss of heat and moisture exchange performed in the upper respiratory tract.
- Desiccation of tracheal epithelium, loss of ciliated cells and metaplasia.
- The presence of a foreign body in the trachea stimulates mucous production; where no cilia are present, this mucociliary stream is arrested.
- The increased mucus is more viscid and thick crusts may form and block the tube.
- Although many patients with a tracheostomy can feed satisfactorily, there is some splinting of the larynx, which may prevent normal swallowing and lead to aspiration; this aspiration may not be apparent.

Postoperative treatment is designed to counteract these effects and frequent suction and humidification are most important.

A trolley must be placed by the bed containing a tracheal dilator, duplicate tubes and introducers, retractors and dressings. Oxygen is at hand and, in the initial period, a nurse must be in constant attendance. Humidification will render the secretions less viscid and a sucker with a catheter attached should be on hand to keep the tracheobronchial tree free from secretions (Summary box 48.11).

Summary box 48.11

Tracheostomy: postoperative management

- Suction – efficient, sterile and as often as required
- Humidification (with or without oxygen)
- A warm, well-ventilated room
- Position of the tube and patient
- Spare tube, introducer, tapes, tracheal dilator
- Change of tube, inner tube, possible speaking valve
- Physiotherapy
- Initiation of local decannulation protocols where indicated

Complications of tracheostomy

The intraoperative, early and late postoperative complications of tracheostomy are listed in Table 48.2.

OTHER EMERGENCY AIRWAY PROCEDURES

Fibreoptic endotracheal intubation

In most emergency situations, endotracheal intubation is the most direct and satisfactory method of securing the airway. Nasotracheal intubation in expert hands is also a well-established technique and is particularly useful if the patient has trismus, severe mandibular injuries, cervical spine rigidity or an obstructing mass within the oral cavity. Both forms of intubation can be facilitated in case of difficulty by passing a fibreoptic endoscope through the centre of an endotracheal tube, hence guiding it into the larynx and trachea under direct vision.

Table 48.2 Tracheostomy: complications.

Intraoperative complications	Haemorrhage Injury to paratracheal structures, particularly the carotid artery, recurrent laryngeal nerve and oesophagus Damage to the trachea
Early postoperative complications	Apnoea caused by a fall in the P_{CO_2} Haemorrhage Subcutaneous emphysema, pneumomediastinum and pneumothorax Accidental extubation, anterior displacement of the tube, obstruction of the tube lumen and tip occlusion against the tracheal wall Infection Swallowing dysfunction
Late postoperative complications	Difficult decannulation Tracheocutaneous fistula Tracheo-oesophageal fistula, tracheoinnominate artery fistula with severe haemorrhage Tracheal stenosis

Laryngeal mask airway

The laryngeal mask airway (LMA) is a wide-bore airway with an inflatable cuff at the distal end, which forms a seal in the pharynx around the laryngeal inlet. Provided the laryngotracheal airway is clear, the LMA provides a clear and secure airway. The technique can easily be learnt by non-anaesthetists and secures an airway in most cases. It comes in a range of sizes covering infants to large adults. It is particularly useful in cases of difficult intubation (Figure 48.41).

Transtracheal ventilation

This technique is simple and effective and allows ventilation for periods in excess of 1 hour providing time to allow for more elective intubation. The cricothyroid membrane is located by palpation of the neck with the index finger, and a 14- or 16-gauge plastic sheathed intravascular needle and a 10-mL syringe containing a few millilitres of lignocaine are introduced into the midline and directed downwards and backwards into the tracheal lumen. The needle is advanced steadily and negative pressure is placed on the syringe until bubbles of air are clearly seen (Figure 48.42). The tissues of the neck may be infiltrated with the anaesthetic if desired and the tracheal mucosa likewise partly anaesthetised by the introduction of 1–2 mL after gaining the lumen. The needle is removed and the plastic sheath cannula remains in the tracheal lumen and must be carefully held and fixed in place by the operator so that it does not come out of the lumen into the soft tissues of the neck. It is attached by means of a Luer connection to the high-pressure oxygen supply. Ventilation may be undertaken in a controlled manner with a jetting device with the chest being observed for appropriate movements.

If there is severe obstruction of the laryngopharynx by the foreign body or tumour, the exhaled outflow of gases can be aided by the placement of one or two further cannulae as exhalation ports. This procedure gains extremely rapid control of ventilation and requires a minimum of technical expertise. Its only notable complication is surgical emphysema of the neck tissues if the cannula dislodges from the tracheal lumen.

Cricothyroidotomy

Cricothyroidotomy has the advantages of speed and ease requiring little equipment and surgical expertise. However, its use for

Figure 48.42 Transtracheal needle introduction.

all but the briefest access to the airway remains controversial and there are conflicting reports with regard to the subsequent incidence of complications, particularly those of subglottic stenosis and long-term voice changes.

The patient's neck is extended and the area between the prominence of the thyroid cartilage and the cricoid cartilage below is palpated with the index finger of the free hand. In the emergency situation, a vertical skin incision is recommended with dissection rapidly carried down to the cricothyroid membrane. A 1-cm transverse incision is made through the membrane immediately above the cricoid cartilage and the scalpel twisted through a right angle to gain access to the airway. If available, artery forceps, dilator or tracheal hook will improve the aperture and insertion of an available tube (Figures 48.43 and 48.44).

Depending on the degree of emergency, it may be necessary for the surgeon to assess the results of the procedure by direct laryngoscopy and the authors recommend that careful consideration should be given to conversion of the cricothyroidotomy to a tracheostomy. Although there is debate about the frequency of subglottic stenosis following this procedure, there is general agreement that it is much increased if any long-term ventilation is undertaken via even a modestly sized tracheostomy tube through the cricothyroid membrane.

LARYNGEAL DISEASE CAUSING VOICE DISORDERS

Vocal nodules

These are fibrous thickenings of the vocal folds at the junction of the middle and anterior third (Figure 48.45), and are the result of vocal abuse; they are known as singers' nodules in adults and screamers' nodules in children. Speech therapy is

Figure 48.41 Laryngeal mask airway being inserted.

therefore the preferred treatment and the lesions will resolve spontaneously in most cases. Occasionally, the nodules will need to be surgically removed using modern microlaryngoscopic dissection or laser techniques, but speech therapy will still be required for postoperative voice rehabilitation (Summary box 48.12).

Figure 48.43 Incision in a cricothyroidotomy.

Figure 48.44 Insertion of a tube after cricothyroidotomy.

Summary box 48.12

Causes of hoarseness

- Mucosal disease, e.g. vocal nodule, polyps or laryngeal papillomatosis, acute or chronic laryngitis
- Neurological disease, e.g. vocal fold palsy
- Neoplasia, e.g. laryngeal tumours
- Non-specific voice disorders, functional dysphonia

Vocal fold polyps

These are usually unilateral and may be associated with an acute infective episode, cigarette smoking and vocal abuse (Figure 48.46). Speech therapy is again indicated, but they do usually require removal by microdissection or laser surgery.

Figure 48.45 Vocal fold nodules.

Figure 48.46 A vocal fold polyp.

Laryngeal papillomata

These are rare benign tumours occurring mainly in children, but can also present in adults. They are most commonly found on the vocal folds, but may spread throughout the larynx and tracheobronchial airway (Figure 48.47). They are caused by papillomaviruses and need removal by carbon dioxide laser or microsurgery to maintain a reasonable voice and airway. These patients are best managed in specialist centres, with the appropriate expertise. Antiviral treatment is of doubtful value at present. Papilloma vaccination is of unproven benefit.

Acute laryngitis

This often occurs in association with upper respiratory tract infections in association with a cough and pharyngitis. Usually viral, it may be localised to the larynx and it settles quickly if the voice is rested during the acute inflammation. Steam inhalations are soothing along with mild analgesia, but antibiotics are unnecessary (Summary box 48.13).

Summary box 48.13

Warning

- Hoarseness lasting for 3–4 weeks should always be referred for an ENT opinion, particularly in smokers

Chronic laryngitis

Chronic laryngitis may be specific and can be caused by mycobacteria, syphilis and fungi. Treatment is directed towards the causative organism. Non-specific laryngitis is common, the main predisposing factors being smoking, chronic upper and lower respiratory sepsis and voice abuse. Gastro-oesophageal reflux has been implicated as a factor in laryngitis, vocal fold nodules and polyps, but the evidence is controversial. There is, however, a vogue for treatment with antireflux medication and proton pump inhibitors. Diagnosis of chronic laryngitis should

Figure 48.47 Laryngeal papillomata.

not be made unless the larynx has been fully evaluated by a laryngologist.

Vocal fold palsy

This may be unilateral or bilateral (Figure 48.48), but a unilateral left vocal fold palsy is the most common because of the long intrathoracic course of the left recurrent laryngeal nerve, which arches around the aorta and may be commonly involved in inflammatory and neoplastic conditions involving the left hilum. Lung cancer is the most common cancer in many parts of the world, and should be considered the cause of a left vocal palsy until proved otherwise.

Other malignant lesions can cause a similar effect and may arise in the nasopharynx, thyroid gland or oesophagus. Bilateral vocal fold paralysis is uncommon and tends to occur after thyroid surgery or head injuries (Summary box 48.14).

Summary box 48.14

Causes of vocal fold palsy

Congenital (infants)

Acquired

- Traumatic
 - Direct to neck
 - Post-surgical, e.g. thyroidectomy
- Infective
 - Viral (rare)
- Neoplastic
 - Carcinoma of the lung involving the left hilum
 - Carcinoma of the larynx
 - Carcinoma of the thyroid
 - Carcinoma of the oesophagus
- Vascular
 - Aortic aneurysm
- Neurological
 - Lower motor neurone disease

Clinical features

Unilateral recurrent laryngeal nerve palsy of sudden onset produces hoarseness, difficulty in swallowing liquids and a weakened cough. These symptoms may be short-lived and the voice may return to normal within a few weeks as the muscles in the opposite vocal fold compensate and move it across the midline to meet the paralysed vocal fold, which usually lies in the paramedian position. Bilateral recurrent laryngeal nerve palsy is an occasional and serious complication of thyroidectomy. Acute

Figure 48.48 Vocal fold positions. (a) Normal; (b) unilateral vocal fold palsy.

dyspnoea occurs as a result of the paramedian position of both vocal folds, which reduce the airway to 2–3 mm and which tend to get sucked together on inspiration. In severe cases, tracheostomy or intubation is necessary immediately, otherwise death occurs from asphyxia.

Investigation of vocal fold paralysis is by a CT scan from skull base (including posterior fossa) to diaphragm. Approximately 20–25 per cent of vocal fold paralysis occurs without known pathology and spontaneous recovery may occur. When compensation does not occur, a unilateral paralysed fold may be medialised by a small external operation on the thyroid cartilage (thyroplasty).

In bilateral vocal fold palsy, surgery may be carried out to remove a small portion of the posterior aspect of one vocal fold or a portion of one arytenoid cartilage. These procedures are most easily performed endoscopically with a carbon dioxide laser. They increase the size of the posterior glottic airway, allowing the patient to be decannulated or even the avoidance of an initial tracheostomy.

TUMOURS OF THE LARYNX

Benign tumours of the larynx are extremely rare. Squamous carcinoma is the most common malignant tumour, being responsible for more than 90 per cent of tumours within the larynx. It is the most common head and neck cancer and previously almost always occurred in elderly male smokers. However, over the past two decades, the incidence among women is rising as a consequence of increased smoking habits. The incidence of laryngeal cancer in the three compartments, supraglottis, glottis and subglottis, varies around the world. The glottis is generally the most common site for cancer in patients in the UK, followed by the supraglottis (Figure 48.49).

Clinical features

Patients almost always present with voice change. If an early diagnosis can be made, i.e. confined to one vocal fold, treatment with radiotherapy or carbon dioxide laser excision is associated with a five-year disease-free survival of approximately 90 per cent. This rate drops dramatically once the lymphatically rich supraglottis or subglottis is involved because of spread to neck nodes. Tumour spread to just one neck gland halves the overall prognosis for the patient.

Investigations

Direct laryngoscopy, preferably a microlaryngoscopy, together with Hopkins' rod examination, allows precise determination of the extent of the tumour and biopsy confirms the histology. CT and MRI give further details of the extent of larger tumours, demonstrating spread outside the larynx and suspicious nodal involvement within the neck, which may not be obvious clinically. The tumour–node–metastasis (TNM) classification of laryngeal cancer is given in Table 48.3.

Treatment

Supraglottic and glottic tumours, stages I and II, are optimally treated with either radiotherapy or endoscopic surgical resection, with the aim of preservation of some function. Subsite location of the primary tumour is an important consideration when selecting the appropriate therapy. Transoral laser resection is a popular surgical treatment modality of stage I and II disease.

Table 48.3 Tumour–node–metastasis (TNM) classification of laryngeal carcinoma.

T – primary tumour

- TX Primary tumour cannot be assessed
- T0 No evidence of primary tumour
- Tis Carcinoma *in situ*
- Supraglottis
 - T1 Tumour limited to one subsite of supraglottis, with normal vocal fold mobility
 - T2 Tumour invades more than one subsite of supraglottis, with normal vocal fold mobility
 - T3 Tumour limited to larynx with vocal fold fixation and/or invades postcricoid area, medial wall of piriform sinus or pre-epiglottic tissues
 - T4 Tumour invades through cartilage and/or extends to other tissues beyond the larynx, e.g. to oropharynx, soft tissues of neck
- Glottis
 - T1 Tumour limited to vocal fold(s) (may involve anterior or posterior commissures) with normal mobility
 - T1a Tumour limited to one vocal fold
 - T1b Tumour involves both vocal folds
 - T2 Tumour extends to supraglottis and/or subglottis, and/or with impaired vocal fold mobility
 - T3 Tumour limited to the larynx with vocal fold fixation
 - T4 Tumour invades through thyroid cartilage and/or extends to other tissues beyond the larynx, e.g. to oropharynx, soft tissues of the neck
- Subglottis
 - T1 Tumour limited to the subglottis
 - T2 Tumour extends to vocal fold(s) with normal or impaired mobility
 - T3 Tumour limited to the larynx with vocal fixation
 - T4 Tumour invades through thyroid cartilage and/or extends to other tissues beyond the larynx, e.g. to oropharynx, soft tissues of the neck

N – regional lymph nodes

- N0 No regional lymph node metastases
- N1 Metastasis in a single ipsilateral lymph node 3 cm or less in greatest diameter
- N2 Metastasis in a single ipsilateral lymph node more than 3 cm or in multiple ipsilateral nodes or in bilateral or contralateral nodes

M – distant metastasis

Figure 48.49 A total laryngectomy specimen with transglottic tumour.

A functional cricoarytenoid must be left intact. Both modalities are associated with similar survival rates. Chemotherapy is generally reserved for those patients with lymph node disease. Complications of organ-sparing treatment include aspiration, which if severe may require salvage laryngectomy.

Advanced laryngeal disease

Advanced stage laryngeal carcinomas (stage III) may be treated with radiotherapy for organ preservation or external partial laryngectomy. Stage IV disease is usually treated with total laryngectomy and adjuvant postoperative radiotherapy. In advanced stage disease chemotherapy is usually employed due to cervical lymph node spread.

After the larynx has been removed (Figure 48.50), the remaining trachea is brought out onto the lower neck as a permanent tracheal stoma and the hypopharynx, which is opened at the time of the operation, is closed to restore continuity for swallowing (Figure 48.51). Thus the upper aero- and digestive tracts are permanently disconnected. Part or all of the thyroid gland and associated parathyroid glands may also be removed, depending on the extent of the disease.

Vocal rehabilitation

The loss of the larynx as a generator of sound does not prevent patients speaking as long as an alternative source of vibration can be created in the pharynx. This can be achieved in one of three ways:

Figure 48.50 Larynx removal at laryngectomy with resultant pharyngeal defect.

Figure 48.51 Transverse closure of the pharynx with an endotracheal tube in the end tracheostome.

- 1 A small one-way valve may be inserted through the back wall of the tracheal stoma into the pharynx. This allows air from the trachea to pass into the pharynx, but does not allow food and liquid to pass into the airway. These valves must not be confused with tracheostomy tubes. Like all foreign bodies, the speaking valves are associated with minor complications, such as the formation of granulations, bleeding or leakage of pharyngeal contents, and have continuing financial cost attached.
- 2 An external device when applied to the soft tissues of the neck produces sound, which is turned into speech by the vocal tract comprising the tongue, pharynx, oral cavity, lips, teeth and nasal sinuses. These devices are usually battery powered.
- 3 Some patients may learn to swallow air into the pharynx and upper oesophagus. On regurgitating the air, a segment of the pharyngo-oesophageal mucosa vibrates to produce sound, which is modified by the vocal tract into speech (Figure 48.52).

THE NECK

Lump in the neck

The correct diagnosis of a lump in the neck can often be made with a careful history and examination. The clinical signs of size, site, shape, consistency, fixation to skin or deep structures, pulsation, compressibility, transillumination or the presence of a bruit still remain as important as ever (Summary box 48.15).

Summary box 48.15

- Bruit

Branchial cyst

A branchial cyst, thought to develop from the vestigial remnants of the second branchial cleft, is usually lined by squamous epithelium, and contains thick, turbid fluid full of cholesterol crystals. The cyst usually presents in the upper neck in early or middle adulthood and is found at the junction of the upper third and middle third of the sternomastoid muscle at its anterior border. It is a fluctuant swelling that may transilluminate and is often soft in its early stages so that it may be difficult to palpate. Other theories hypothesise that branchial cysts develop from cystic transformation of cervical lymph nodes.

If the cyst becomes infected, it becomes erythematous and tender and, on occasions, it may be difficult to differentiate from a tuberculous abscess. Ultrasound and fine-needle aspiration

Figure 48.52 A Blom-Singer valve with a tracheo-oesophageal fistula.

both aid diagnosis, and treatment is by complete excision, which is best undertaken when the lesion is quiescent. Although the anterior aspect of the cyst is easy to dissect, it may pass backwards and upwards through the bifurcation of the common carotid artery as far as the pharyngeal constrictors. It passes superficial to the hypoglossal and glossopharyngeal nerves, but deep to the posterior belly of the digastric. These structures and the spinal accessory nerve must be positively identified to avoid damage.

Branchial fistula

A branchial fistula may be unilateral or bilateral and is thought to represent a persistent second branchial cleft. The external orifice is nearly always situated in the lower third of the neck near the anterior border of the sternocleidomastoid, while the internal orifice is located on the anterior aspect of the posterior faucial pillar just behind the tonsil. However, the internal aspect of the tract may end blindly at or close to the lateral pharyngeal wall, constituting a sinus rather than a fistula. The tract is lined by ciliated columnar epithelium and, as such, there may be a small amount of recurrent mucous or mucopurulent discharge onto the neck. The tract follows the same path as a branchial cyst and requires complete excision, often by more than one transverse incision in the neck (Figure 48.53).

Cystic hygroma

Cystic hygromas usually present in the neonate or in early infancy, and occasionally may present at birth and be so large as to obstruct labour. The cysts are filled with clear lymph and

lined by a single layer of epithelium with a mosaic appearance (Figure 48.54). Swelling usually occurs in the neck and may involve the parotid, submandibular, tongue and floor of mouth areas. The swelling may be bilateral and is soft and partially compressible, visibly increasing in size when the child coughs or

cries. The characteristic that distinguishes it from all other neck swellings is that it is brilliantly translucent. The cheek, axilla, groin and mediastinum are other less frequent sites for a cystic hygroma.

The behaviour of cystic hygromas during infancy is unpredictable. Sometimes the cyst expands rapidly and occasionally respiratory difficulty ensues, requiring immediate aspiration and even, occasionally, a tracheostomy. The cyst may become infected.

Definitive treatment is complete excision of the cyst at an early stage. Injection of a sclerosing agent, for example picibanil (OK-432), may reduce the size of the cyst; however, they are commonly multicystic and if the injection is extracystic subsequent surgery may be more difficult.

Thyroglossal duct cysts

Embryology

The thyroid gland descends early in fetal life from the base of the tongue towards its position in the lower neck with the isthmus lying over the second and third tracheal rings. At the time of its descent, the hyoid bone has not been formed and the track of the descent of the thyroid gland is variable, passing in front, through or behind the eventual position of the hyoid body. Thyroglossal duct cysts represent a persistence of this track and may therefore be found anywhere in or adjacent to the midline from the tongue base to the thyroid isthmus. Rarely, a thyroglossal cyst may contain the only functioning thyroid tissue in the body.

Clinical features

The cysts almost always arise in the midline but, when they are adjacent to the thyroid cartilage, they may lie slightly to one side of the midline. Classically, the cyst moves upwards on swallowing and with tongue protrusion, but this can also occur with other midline cysts such as dermoid cysts, as it merely indicates attachment to the hyoid bone.

Figure 48.53 (a) Plain radiograph with radio-opaque dye in the fistula tract. (b) Probing of the fistula tract. (c) Excision of the fistula tract.

Figure 48.54 Cystic hygroma.

Thyroglossal cysts may become infected and rupture onto the skin of the neck presenting as a discharging sinus. Although they often occur in children, they may also present in adults, even as late as the sixth or seventh decade of life (Figure 48.55).

Treatment

Treatment must include excision of the whole thyroglossal tract, which involves removal of the body of the hyoid bone and the suprahyoid tract through the tongue base to the vallecula at the site of the primitive foramen caecum, together with a core of tissue on either side. This operation is known as Sistrunk's operation and prevents recurrence, most notably from small side branches of the thyroglossal tract.

TRAUMA TO THE NECK

Wounds above the hyoid bone

The cavity of the mouth or pharynx may have been entered and the epiglottis may be divided via the pre-epiglottic space. These wounds require repair with absorbable sutures on a formal basis under a general anaesthetic. If there is any degree of associated oedema or bleeding, particularly in relation to the tongue base or laryngeal inlet, it is advisable to perform a tracheostomy to avoid any subsequent respiratory distress.

Figure 48.55 A patient with thyroglossal fistula from a cyst in the midline of the neck.

Wounds of the thyroid and cricoid cartilage

Blunt crushing injuries or severe laceration injuries to the laryngeal skeleton can cause marked haematoma formation and rapid loss of the airway. There may be significant disruption of the laryngeal skeleton. These patients should not have an endotracheal intubation for any length of time, even if this is the initial emergency way of protecting the airway. The larynx is a delicate three-tiered sphincter and the presence of a foreign body in its lumen after severe disruption gives rise to major fibrosis and loss of laryngeal function. These injuries are frequently an absolute indication for a low tracheostomy, following which the larynx can be carefully explored, damaged cartilages repositioned and sutured, and the paraglottic space drained.

An indwelling stent of soft sponge shaped to fit the laryngeal lumen and held by a nylon retaining suture through the neck may be left in place for approximately 5 days. This stent can be removed endoscopically after cutting the retaining suture and, as the laryngeal damage heals, the patient may then be decannulated.

Division of the trachea

Wounds of the trachea are rare. They should all be formally explored and, in order to obtain adequate exposure, it is usually necessary to divide and ligate the thyroid isthmus. A small tracheostomy below the wound followed by repair of the trachea with a limited number of submucosal sutures is appropriate. In self-inflicted wounds, the recurrent laryngeal nerves, which lie protected in the tracheo-oesophageal grooves, are rarely injured. Primary repair is rarely possible but may be undertaken at the time of formal exploration of a major neck wound.

Neurovascular injury

Penetrating wounds of the neck may involve the common carotid or the external or internal carotid arteries. Major haemorrhagic shock may occur. Venous air embolism may occur as a result of damage to one of the major veins, most commonly the internal jugular. Compression, resuscitation and exploration under general anaesthetic, with control of vessels above and below the injury, and primary repair should be undertaken. All cervical nerves are vulnerable to injury, particularly the vagus and recurrent laryngeal nerves and cervical sympathetic chain.

Thoracic duct injury

Wounds to the thoracic duct are rare and most often occur in association with dissection of lymph nodes in the left supraclavicular fossa. When damage to the duct is not recognised at the time of operation, chyle may subsequently leak from the wound in amounts up to 2 litres per day with profound effects on nutrition.

Treatment

Should the damage be recognised during an operation, the proximal end of the duct must be ligated. Ligation of the duct is not harmful because there are a number of anastomotic channels between the lymphatic and venous system in the lower neck. If undetected, chyle usually starts to discharge from the neck wound within 24 hours of the operation. On occasion, firm pressure by a pad to the lower neck may stop the leakage, but frequently this is unsuccessful and the wound should be re-explored and the damaged duct ligated.

Inflammatory conditions of the neck

Ludwig's angina

Ludwig described a clinical entity characterised by a brawny swelling of the submandibular region combined with inflammatory oedema of the mouth. It is these combined cervical and intraoral signs that constitute the characteristic feature of the lesion, as well as the accompanying putrid halitosis.

The infection is often caused by a virulent streptococcal infection associated with anaerobic organisms and sometimes with other lesions of the floor of the mouth, such as carcinoma. The infection encompasses both sides of the mylohyoid muscle causing oedema and inflammation such that the tongue may be displaced upwards and backwards, giving rise to dysphagia and subsequently to painful obstruction of the airway. Unless treated, cellulitis may extend beneath the deep fascial layers of the neck to involve the larynx, causing glottic oedema and airway compromise.

Antibiotic therapy should be instituted as soon as possible using intravenous broad-spectrum antibiotics, with additional anaerobic cover.

In advanced cases when the swelling does not subside rapidly with such treatment, a curved submental incision may be used to drain both submandibular triangles. The mylohyoid muscle may be incised to decompress the floor of the mouth and corrugated drains placed in the wound, which is then lightly sutured. This operation may be conducted under local anaesthetic. Rarely, a tracheostomy may be necessary.

Cervical lymphadenitis

Cervical lymphadenitis is common due to infection or inflammation in the oral and nasal cavities, pharynx, larynx, ear, scalp and face.

Acute lymphadenitis

The affected lymph nodes are enlarged and tender, and there may be varying degrees of general constitutional disturbance such as pyrexia, anorexia and general malaise. The treatment in the first instance is directed to the primary focus of infection, for example tonsillitis or a dental abscess.

Chronic lymphadenitis

Chronic, painless lymphadenopathy may be caused by tuberculosis in young children or adults, or be secondary to malignant disease, most commonly from a squamous carcinoma in older individuals. Lymphoma and/or HIV infection may also present in the cervical nodes (Summary box 48.16).

Tuberculous adenitis

The condition most commonly affects children or young adults, but can occur at any age. The deep upper cervical nodes are most commonly affected, but there may be a widespread cervical lymphadenitis with many matting together. In most cases, the tubercular bacilli gain entrance through the tonsil of the corresponding side as the lymphadenopathy. Both bovine and human tuberculosis may be responsible. In approximately 80 per cent of patients, the tuberculous process is limited to the clinically affected group of lymph nodes, but a primary focus in the lungs must always be suspected.

As renal and pulmonary tuberculosis occasionally coexist, the urine should be examined carefully. Rarely, the patient may

Summary box 48.16

 - Occult primary

develop a natural resistance to the infection and the nodes may be detected at a later date as evidenced by calcification on radiography. This can also be seen after appropriate general treatment of tuberculosis adenitis. If treatment is not instituted, the caseated node may liquefy and break down with the formation of a cold abscess in the neck. The pus is initially confined by the deep cervical fascia, but after weeks or months, this may become eroded at one point and the pus flows through the small opening into the space beneath the superficial fascia. The process has now reached the well-known stage of a 'collar-stud' abscess. The superficial abscess enlarges steadily and, unless suitably treated, a discharging sinus results.

Investigation

Fine-needle aspirate taken from neck nodes with a suspicion of tuberculosis should be tested for the presence of acid-fast bacilli. Systemic investigation should not be neglected, with chest x-ray and Mantoux testing useful first-line investigations. Depending on the country of origin, where tuberculosis is diagnosed or suspected, the coexistence of other infectious diseases, such as HIV and malaria, should not be overlooked.

Treatment

The patient should be treated by appropriate chemotherapy, dependent on the sensitivities derived from the abscess contents. If an abscess fails to resolve despite appropriate chemotherapy and general measures, occasionally excision of the abscess and its surrounding fibrous capsule is necessary, together with the relevant lymph nodes. If there is active tuberculosis of another system, for example pulmonary tuberculosis, then removal of tuberculous lymph nodes in the neck is inappropriate. The nodes are commonly related to the internal jugular vein, common carotid and vagus nerve, and are usually associated with significant fibrosis making surgery difficult. A portion of the internal jugular vein may require excision, taking considerable care to avoid damage to the vagus or the cervical sympathetic trunk. To facilitate access, the sternocleidomastoid muscle

should be divided, particularly if the disease is adjacent to the spinal accessory nerve or the hypoglossal nerve. The resected nodes should be sent for both histology and microbiology.

PRIMARY TUMOURS OF THE NECK

Neurogenic tumours

Chemodectoma (carotid body tumour)

This is a rare tumour that has a higher incidence in areas where people live at high altitudes because of chronic hypoxia leading to carotid body hyperplasia. The tumours most commonly present in the fifth decade and approximately 10 per cent of patients have a family history. There is an association with phaeochromocytoma. The tumours arise from the chemoreceptor cells on the medial side of the carotid bulb and, at this point, the tumour is adherent to the carotid wall. The cells of the chemodectoma are not hormonally active and the tumours are usually benign with only a small number of cases producing proven metastases.

Clinical features

There is often a long history of a slowly enlarging, painless lump at the carotid bifurcation. About one-third of patients present with a pharyngeal mass that pushes the tonsil medially and anteriorly. The mass is firm, rubbery, pulsatile, mobile from side to side but not up and down, and can sometimes be emptied by firm pressure, after which it slowly refills in a pulsatile manner. A bruit may also be present. Swellings in the parapharyngeal space, which often displace the tonsil medially, should not be biopsied from within the mouth.

Investigations

When a chemodectoma is suspected, a carotid angiogram can be carried out to demonstrate the carotid bifurcation, which is usually splayed, and a blush, which outlines the tumour vessels. MRI scanning also provides excellent detail in most cases. This tumour must not be biopsied and fine-needle aspiration is also contraindicated.

Treatment

Because these tumours rarely metastasise and their overall rate of growth is slow, the need for surgical removal must be considered carefully as complications of surgery are potentially serious. The operation is best avoided in elderly patients. Radiotherapy has no effect. In some cases, it may be possible to dissect the tumour away from the carotid bifurcation but, at times, when the tumour is large, it may not be separable from the vessels and resection will be necessary, such that all appropriate facilities should be available to establish a bypass while a vein graft is inserted to restore arterial continuity in the carotid system.

Vagal body tumours

Vagal paragangliomas arise from nests of paraganglionic tissue of the vagus nerve just below the base of the skull near the jugular foramen. They may also be found at various sites along the nerve down to the level of the carotid artery bifurcation (Figure 48.56).

They also present as slowly growing and painless masses in the anterolateral aspect of the neck, and may also have a long

Figure 48.56 Sites for neurogenic tumours (paragangliomas) in the neck.

history, commonly of 2–3 years, before diagnosis. They may spread into the cranial cavity. Diagnosis is confirmed by CT and MRI scanning and additional MR angiogram or arteriography if necessary. Treatment is surgical excision.

Peripheral nerve tumours

Schwannomas are solitary and encapsulated tumours attached to or surrounded by nerve, although paralysis of the associated nerve is unusual. The vagus nerve is the most common site. Neurofibromas also arise from the Schwann cell and may be part of von Recklinghausen's syndrome of multiple neurofibromatosis. Multiple neurofibromatosis is an autosomal dominant, hereditary disease and the neurofibromata may be present at birth and often multiply.

Diagnosis requires CT or MRI scanning to differentiate them from other parapharyngeal tumours but, on occasions, the diagnosis must wait until excision.

Secondary carcinoma

Metastatic spread of squamous carcinoma to the cervical lymph nodes is a common occurrence from head and neck primary cancers. The nasopharynx, tonsil, tongue, pyriform fossa and supraglottic larynx must be carefully examined by panendoscopy for the primary growth before considering biopsy or any surgery on the neck. Investigation is further assisted by ultrasound and fine-needle aspirate of the neck node.

Management

The management of malignant cervical lymph nodes depends on the overall treatment regime:

- If surgery is being used to treat the primary disease and the cervical nodes are palpable and >3 cm, they may be excised with the primary lesion.
- If radiotherapy is used initially, as is always the case in carcinoma of the nasopharynx, then radiotherapy may also be given to the neck nodes, whatever their stage. In the case of the tongue, pharynx or larynx, however, if the node exceeds 3 cm in diameter, then surgery may be necessary for the neck nodes, even if the primary tumour is treated by chemoradiation.
- If radiotherapy is used initially with resolution of the primary tumour, but there is subsequent residual or recurrent nodal disease, then this situation will require cervical lymph node dissection.

Type of neck dissection

Classical radical neck dissection (Crile)

The classic operation involves resection of the cervical lymphatics and lymph nodes and those structures closely associated: the internal jugular vein, the accessory nerve, the submandibular gland and the sternocleidomastoid muscle. These structures are all removed *en bloc* and in continuity with the primary disease if possible. The main disability that follows the operation is weakness and drooping of the shoulder due to paralysis of the trapezius muscle as a consequence of excision of the accessory nerve.

Modified radical neck dissection

In selected cases, one or more of the three following structures are preserved: the accessory nerve, the sternocleidomastoid muscle or the internal jugular vein. Otherwise, all major lymph node groups and lymphatics are excised. Whichever structures are preserved should be clearly noted.

George Washington Crile, 1864–1943, Professor of Surgery, Western Reserve University and one of the founders in 1921 of The Cleveland Clinic, Cleveland, OH, USA. He devised the small haemostatic forceps that goes by his name.

Selective neck dissection

In this type of dissection, one or more of the major lymph node groups is preserved along with the sternocleidomastoid muscle, accessory nerve and internal jugular vein. In these circumstances, the exact groups of nodes excised must be documented.

SUMMARY

The anatomical and physiological performance of the pharyngolarynx is involved in the important mechanisms of breathing, coughing, voice production and swallowing. A variety of congenital, traumatic, infectious and neoplastic conditions disturb these functions, giving rise to the common symptoms of pain, swelling, hoarseness, dyspnoea and dysphagia.

Squamous carcinomas are the most common malignancies, accounting for approximately 80 per cent of all head and neck tumours. Their incidence and anatomical site vary around the world, but they are mainly caused by the preventable aetiological agents of smoking and alcohol, although nasopharyngeal squamous carcinomas have additional genetic and environmental factors. These head and neck cancers have a high morbidity and mortality, and require expert treatment.

CHAPTER
49Oropharyngeal
cancer

LEARNING OBJECTIVES

To understand:

- The relationship between oral cancers and the use of alcohol and tobacco
- The cardinal features of oropharyngeal cancer
- The investigation and treatment of patients with oropharyngeal cancer

INTRODUCTION AND EPIDEMIOLOGY

In the Western world, oral/oropharyngeal cancer is uncommon, accounting for only 2–4 per cent of all malignant tumours, although there is increasing evidence that the incidence is on the increase, particularly among young people. In the Indian subcontinent, however, oropharyngeal cancer remains the most common malignant tumour, accounting for 40 per cent of all cancers.

Epidemiology

The principal aetiological agents are tobacco and alcohol. In Europe and North America, this is mainly through cigarette smoking combined with alcohol abuse. Synergism between alcohol abuse and tobacco use in the development of squamous cell carcinoma (SCC) of the head and neck is well established, although evidence is gathering that the human papillomavirus (HPV16) is becoming increasingly responsible for tumours that arise particularly in the oropharynx of younger/middle-aged patients. Risk factors associated with cancer of the head and neck are outlined in Summary box 49.1.

Summary box 49.1**Risk factors associated with cancer of the head and neck**

- Tobacco
- Alcohol
- Areca nut/pan masala
- Human papillomavirus
- Epstein–Barr virus
- Plummer–Vinson syndrome
- Poor nutrition

In the Indian subcontinent, the use of ‘pan’ (a combination of betel nut, areca nut, lime and tobacco) as well as reverse smoking (smoking a cheroot with the burning end inside the mouth) are responsible for the high incidence of oropharyngeal

cancer. Betel quid appears to be the major carcinogen, although there is also a relationship between slaked lime and the areca nut and cancer.

INCIDENCE

The incidence is greater in men than in women and it is predominantly a disease of the elderly (those over 60 years of age). The incidence in women is increasing, particularly in younger patients, with oral tongue cancer being the cancer that is usually, but not exclusively, present.

ANATOMY**Lip and oral cavity**

The oral cavity extends from the skin–vermillion border of the lips anteriorly to the junction of the soft palate superiorly and the line of the circumvallate papillae on the junction of the posterior one-third and anterior two-thirds of the tongue posteriorly. The anatomical sites that are frequently involved in mouth cancer include the floor of the mouth, the lateral border of the anterior tongue and the retromolar trigone (Figure 49.1). The retromolar trigone is defined as the attached mucosa overlying the ascending ramus of the mandible posterior to the last molar tooth and extending superiorly to the maxillary tuberosity.

Oropharynx

The oropharynx extends vertically from the oral surface of the soft palate to the superior surface of the hyoid bone (floor of vallecula). This includes the base of the tongue, the soft palate and the anterior and posterior tonsillar pillars, as well as the pharyngeal tonsils and the lateral and posterior pharyngeal walls. The

In India, habitual chewing of the rolled betel leaf with betel nut inside it with concentrated lime and storing the quid over long periods inside the cheek results in a high incidence of cancer of the cheek. Another routine habit among southern Indian rural dwellers is to roll the tobacco leaf and then smoke by putting the lighted end into the oral cavity; this almost always results in cancer of the palate or some other part of the oral cavity.

Figure 49.1 Common anatomical sites (blue) for oral squamous cell carcinoma.

lateral boundaries include the pharyngeal constrictor muscles and the medial aspect of the mandible.

PATHOLOGY

The anatomy of the oral cavity and the oropharynx is complex and the course of the nerves, blood vessels, lymphatic pathways and fascial planes influences the spread of disease. Fascial planes, including the periosteum, serve as barriers to the direct spread of tumours but contribute to the spread of tumours into the cervical lymph nodes. Perineural invasion acts as a conduit for the direct spread of tumours and profoundly impacts on prognosis and survival. Angioinvasion also carries a negative prognosis and correlates directly with distant metastases, particularly of oral tongue cancer.

Histology

Squamous cell carcinoma is the predominant histology for tumours arising in the oral cavity and oropharynx. Tumours mainly arise from the mucosal epithelium, although malignant salivary gland tumours from the minor salivary glands are a rare but important group of lesions. Lymphomas, particularly around Waldeyer's ring (tonsils, tongue base, lingual tonsil regions, posterior one-third of the tongue (see Figure 48.2, p. 674)), make up the last of the three principal pathological groups of oropharyngeal cancer.

Chronic exposure of the mucosal surface to carcinogenic substances, i.e. tobacco and alcohol, can produce multiple sub-clinical sites of carcinoma that can at any stage develop into malignant tumour. This pathological process supports the preventative measures of smoking cessation and alcohol rehabilitation in patients with head and neck cancer, thereby minimising the occurrence of synchronous and metachronous tumours (see below under Field changes and second primary tumours).

Premalignant lesions

The majority of oral carcinomas are not preceded by or associated with clinically obvious premalignant lesions. There is,

however, a group of oral pathological conditions in which an association with malignant transformation exists (Summary box 49.2).

Summary box 49.2

Conditions associated with malignant transformation

High-risk lesions

- Erythroplakia
- Speckled erythroplakia
- Chronic hyperplastic candidiasis

Medium-risk lesions

- Oral submucous fibrosis
- Syphilitic glossitis
- Sideropenic dysphagia (Paterson–Kelly syndrome)

Low-risk/equivocal-risk lesions

- Oral lichen planus
- Discoid lupus erythematosus
- Discoid keratosis congenita

Clinical features

Premalignant lesions of the oral mucosa and oropharyngeal mucosa present as either:

- leukoplakia
- speckled leukoplakia
- erythroplakia/plasia.

Leukoplakia

Leukoplakia is defined as any white patch or plaque that cannot be characterised clinically or pathologically. It is purely a descriptive term with no histological correlation. Leukoplakia varies from a small, well-circumscribed, homogenous white plaque to an extensive lesion involving large surface areas of the oral mucosa. It may be smooth or wrinkled, fissured and vary in colour depending on the thickness of the lesion.

Speckled leukoplakia

This is a variation of leukoplakia arising on an erythematous base (Figure 49.2). It has the highest rate of malignant transformation.

Figure 49.2 Speckled leukoplakia on the lateral border of the tongue. Histology confirms carcinoma *in situ*.

Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921, Professor of Pathological Anatomy, Berlin, Germany.

Donald Rose Paterson, 1863–1939, surgeon, Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, Wales.

Adam Brown Kelly, 1865–1941, surgeon, Ear, Nose and Throat Department, The Royal Victoria Infirmary, Glasgow, Scotland.

Erythroplakia

Erythroplakia is defined as any lesion of the oral mucosa that presents as a bright red plaque which cannot be characterised clinically or pathologically as any other recognisable condition. The lesions are irregular in outline and separated from adjacent normal mucosa (Figure 49.3). The surfaces may be nodular. These lesions occasionally coexist with leukoplakia.

FIELD CHANGE AND SECOND PRIMARY TUMOURS

The diffuse and chronic exposure of the mucosa of the upper aerodigestive tract to carcinogenic substances, e.g. tobacco and alcohol, causes widespread adverse changes in the mucosal epithelium. The consequence of the diffuse exposure is the development of separate tumours at different anatomical sites. These may present simultaneously, within six months (synchronous) or may be delayed (metachronous). Slaughter, in 1950, first proposed the concept of field change or 'cancerisation'. Separate primary tumours may not represent distinct genetic mutational events but rather the same clonal origin of cells, which migrate to separate sites in the upper aerodigestive tract. Nevertheless, minimising exposure of the oropharyngeal tissues to potential insults is the cornerstone of long-term management for patients with head and neck cancer.

Patients who develop a first tumour in the oral cavity and the oropharynx are more likely to develop a second primary tumour in the upper oesophagus. The overall rate of second primary tumour development is 15 per cent. In total, 80 per cent of these are metachronous tumours, of which 50 per cent develop within the first two years of initial presentation (Figure 49.4). The prevalence of synchronous second primary tumours is 4 per cent.

Potential for malignant change

The potential risk for malignant transformation:

- increases with increasing age of the patient;
- increases with increasing age of the lesion;
- is higher in smokers;
- increases with alcohol consumption;
- depends on the anatomical site of the premalignant lesion;
- is particularly high for leukoplakia on the floor of the mouth

Figure 49.3 Erythroplakia of the left soft palate and lateral pharyngeal wall.

and ventral surface of the tongue, particularly in younger women, even in the absence of associated risk factors.

PREMALIGNANT CONDITIONS

Chronic hyperplastic candidiasis

Chronic hyperplastic candidiasis produces dense plaques of leukoplakia, particularly around the commissures of the mouth. The lesions occasionally extend on to the vermilion and even the facial skin (Figure 49.5). These lesions have a high incidence of malignant transformation, thought to be the result of invasion of the lesion by *Candida albicans*. A small percentage of patients have an associated immunological defect, which encourages the invasion of *C. albicans*, rendering the patient susceptible to malignant transformation. Specific management of chronic hyperplastic candidiasis includes prolonged (6 weeks) topical antifungal treatment or systemic antifungal treatment (2 weeks). If the lesions persist after medical therapy, surgical excision or laser vaporisation is strongly recommended.

Oral submucous fibrosis

Oral submucous fibrosis is a progressive disease in which fibrous bands form beneath the oral mucosa. Scarring produces con-

Figure 49.4 Metachronous tumour in the right mandibular alveolus after previous partial glossectomy and forearm flap reconstruction.

Figure 49.5 Chronic hyperplastic candidiasis of the left buccal mucosa.

tracture, resulting in limited mouth opening and restricted tongue movement. The condition is almost entirely confined to the Asian population and is characterised pathologically by epithelial fibrosis with associated atrophy and hyperplasia of the overlying epithelium (Figure 49.6). The epithelium also shows changes of epithelial dysplasia. Restricted mouth opening can be treated with either intralesional steroids or surgical excision and skin grafts.

Research strongly indicates that oral submucous fibrosis is significantly associated with the use of pan masala areca nut, with or without concurrent alcohol use. Tobacco smoking alone is not associated with oral submucous fibrosis.

Sideropenic dysphagia (Plummer-Vincent and Paterson-Kelly syndromes)

There is a well-known relationship between sideropenia (iron deficiency in the absence of anaemia) and the development of oral cancer. Sideropenia is common in Scandinavian women and leads to epithelial atrophy, which renders the oral mucosa vulnerable to irritation from topical carcinogens. Correction of the sideropenia with iron supplements reduces the epithelial atrophy and risk of malignant transformation.

CLASSIFICATION AND STAGING

TNM staging

Staging of head and neck cancer is defined by the American Joint Committee on Cancer (AJCC) and follows the TNM system. The system also takes into account the pretreatment computed tomography (CT) or magnetic resonance imaging (MRI) of the tumour. The T classification indicates the extent of the primary tumour and the N classification relates to the extent of regional neck metastases to the cervical lymph nodes; this is identical for all mucosal sites of the head and neck except for the nasopharynx. The M classification relates to distant metastasis. The risk of distant metastasis is dependent on nodal disease rather than the size of the primary tumour. Tumours close to the midline are at a greater risk of developing bilateral or contralateral cervical node metastasis.

The TNM staging system is outlined in Table 49.1.

Figure 49.6 Oral submucous fibrosis of the right buccal mucosa and soft palate.

Table 49.1 The TNM staging system.

Primary tumour (T)

TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma <i>in situ</i>
T1	Tumour <2 cm in greatest dimension
T2	Tumour >2 but <4 cm
T3	Tumour >4 cm but <6 cm
T4	Tumour invades adjacent structures, e.g. mandible, skin

Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node <3 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node >3 cm but not more than 6 cm
N2b	Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension
N3	Metastasis in any lymph node >6 cm

Distant metastasis

M0	No evidence of distant metastasis
M1	Evidence of distant metastasis

Stage

O	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1, T2, T3	N1	M0
IV	T4	N0	M0
	Any T	N2	M0
	Any T	N3	M0
	Any T	Any N	M1

Patterns of lymph node metastasis

The cervical lymph nodes are divided into five principal levels as outlined in Figure 49.7.

The spread of tumour from the primary site has been well addressed. SCC in the oral cavity and lips tends to metastasise to lymph nodes at levels I, II and III. However, with SCC of the oral tongue there is a risk of skip metastasis directly to lymph node levels III or IV, without the involvement of higher-level lymph node groups. Tumours arising in the oropharynx commonly metastasise to lymph node levels II, III and IV, as well as retropharyngeal and contralateral nodal groups.

Distant metastases are relatively uncommon but sites involved include lung, brain, liver, bone and skin.

CLINICAL FEATURES

Between 25 and 50 per cent of patients with cancer of the oral cavity or oropharynx present late. Many of these patients are elderly and frail and delay visiting the doctor or the dentist partly because they wear dentures and are accustomed to the discomfort and associated ulceration. Occasionally, dental and medical practitioners fail to recognise that a lesion may be

Figure 49.7 Cervical lymph nodes: (I) submandibular; (II) upper jugular; (III) middle jugular; (IV) lower jugular; (V) posterior triangle.

malignant and further delay referral. Moreover, early oral cancer is usually not painful until either the ulcer becomes infected or the tumour invades local sensory nerve fibres. Clinical presentation is markedly dependent on the anatomical site.

Lip cancer

Lip cancer presents early as it is readily visible to the patient. It usually arises as an ulcer on the vermilion border (Figure 49.8). In total, 95 per cent of carcinomas of the lip arise on the lower lip and 15 per cent arise in the central one-third and commissures. Tumours tend to spread laterally over the mucosal surface. Lymph node metastases, usually to the submental or submandibular nodes, occur late.

Oral cavity

Cancers of the oral cavity present in a variable way (Figure 49.9) but are often associated with persisting swelling or ulceration within the oral cavity (Summary box 49.3).

The duration of symptoms is highly variable, from several weeks to many months.

Figure 49.8 Squamous cell carcinoma of the lower lip.

Summary box 49.3

Clinical features of oral cancer

- Persistent oral swelling for >4 weeks
- Mouth ulceration for >4 weeks
- Sore tongue
- Difficulty swallowing
- Jaw or facial swelling
- Painless neck lump
- Unexplained tooth mobility
- Trismus

Oropharynx

Cancer of the oropharynx frequently presents much later than cancer of the lip and oral cavity. An ipsilateral or contralateral lump in the neck may be the single presenting complaint from a patient with a carcinoma arising from the tongue base, tonsil or soft palate. Palpable asymmetry, particularly in the tonsil, often represents submucosal infiltration of tumour. Deeper infiltration of the tongue base, pterygoid muscles or adherence of the tumour to the jaw results in poor mobility of the tongue or palate. Common clinical features of oropharyngeal cancer are outlined in Summary box 49.4.

Figure 49.9 (a) Ulcerative squamous cell carcinoma of the anterior floor of the mouth. (b) Exophytic squamous cell carcinoma of the right lateral border of the tongue.

Summary box 49.4

Clinical features of oropharyngeal cancer

- Localised and persistent sore throat
- Difficulty and/or painful swallowing for >4 weeks
- Painless neck lump
- Unilateral tonsillar enlargement or ulceration
- Otolgia

INVESTIGATIONS

When a clinical diagnosis of oropharyngeal cancer is suspected, a comprehensive protocol of investigations should be instituted. An incisional biopsy should be carried out in all cases. Formal examination under anaesthetic is preferred in the vast majority of cases, not only to carry out the biopsy, but also to palpate and examine the extent of the tumour, which can be exquisitely tender in the conscious patient. Under the same anaesthetic, extraction of teeth with a dubious prognosis can be performed. Where available, and when the diagnosis is clear-cut, insertion of a percutaneous endoscopic gastrostomy (PEG) should be performed to facilitate feeding in the treatment phase. The biopsy should be generous and include the most suspicious area of the lesion, as well as normal adjacent tissue. Areas of necrosis or gross infection should be avoided.

Radiography

Plain radiography of the jaw is of limited value but does provide an opportunity for dental assessment. Before examination under anaesthesia, an orthopantomogram of the jaws is helpful to assess bony invasion, particularly from tumours arising on the alveolus and maxillary antrum.

Magnetic resonance imaging

MRI is the investigation of choice for cancer of the oral cavity and oropharynx, as it is not distorted by metallic dental restorations and provides excellent visualisation of soft-tissue infiltration of the tumour (Figure 49.10). Ideally, it should be performed before diagnostic biopsy as biopsy frequently distorts the image of the primary tumour. The specificity and sensitivity of MRI in diagnosing cervical node metastasis are similar to that of CT. Patients who suffer with claustrophobia may have difficulty in tolerating the investigation.

Computed tomography

CT is much more widely available than MRI but has limited value in oral cavity and oropharyngeal cancer. It is useful when bony invasion is suspected. CT of the thorax and abdomen is now indicated for all patients and not just those with proven cervical lymph node metastasis and large-volume disease.

Radionuclide studies

A radioisotope bone scan of the facial skeleton adds little to the diagnosis and assessment of oropharyngeal cancer. The scan is not specific and tends to show increased uptake wherever there is increased metabolic activity in bone. A false-positive diagnosis is common and 'over-staging' of the disease frequent.

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is useful for the assessment and pathological diagnosis of enlarged cervical lymph

Figure 49.10 Magnetic resonance imaging of a primary tumour of the left tongue base (blue arrow) and neck node metastasis (red arrow).

nodes. It involves the use of a fine-needle puncture into the mass and immediate aspiration for cytological examination. It has few complications and does not spread tumour. It requires no specialist equipment other than a 21G or 23G needle and a 10-mL syringe. Aspiration should be carried out only when the needle enters the swelling. If the specimen can be assessed immediately by an expert cytologist, then it can be sent without fixation. If there is delay in microscopic examination, then the specimen, smeared on a microscope slide, should be fixed before transfer to the laboratory. The positive yield from FNAC is dependent not only on the quality of the aspirate, but also on the skill of the cytologist.

Ultrasound

Ultrasound has limited use in the management of oropharyngeal cancer. It is useful as an adjunct in FNAC to ensure accurate aspiration of a deeply seated neck node swelling.

TREATMENT

General principles

The two principal treatment modalities of oropharyngeal cancer are surgery and radiotherapy. Small tumours can be managed either by primary radiotherapy or surgery. Large-volume disease, i.e. advanced tumour, usually requires a combination of surgery and radiotherapy. There is an increasing move to manage extensive disease of the oropharynx with chemoradiotherapy, provided that patients are medically fit to tolerate the toxicity. Factors that need to be taken into consideration include:

- the site of disease
- the stage

- histology
- concomitant medical disease
- social factors.

The management of head and neck cancer involves a team approach, whereby patients are assessed objectively by several specialists who agree on an optimum treatment strategy.

Cancer of the oral cavity is frequently managed with primary surgery whereas cancer of the oropharynx can be treated with either primary radiotherapy or primary surgery, or a combination, i.e. surgery for neck nodes and radiotherapy for the primary site.

When the tumour invades bone, e.g. the mandible, primary surgery is deemed appropriate as radiotherapy is less effective in controlling disease. Surgery is also more appropriate for bulky advanced disease, usually followed by postoperative radiotherapy. Tumours of intermediate size, e.g. T2 and T3 tumours, are more problematic and treatment regimes more controversial, hence the need for planning by a multidisciplinary team.

Cervical node involvement

When cervical lymph node involvement occurs, treatment should be geared towards a single modality to deal simultaneously with the lymph node disease and the primary tumour.

Histology

The degree of differentiation of SCC does not normally influence the management of the tumour alone. Management of verrucous carcinoma, a variant of SCC, is identical to that of any other SCC.

Malignant tumours of the minor salivary glands require primary surgery whereas lymphoma is managed by radiotherapy, or chemotherapy and radiotherapy, depending on the stage. Postoperative radiotherapy for minor salivary gland tumours is often indicated to reduce the risk of locoregional recurrence.

Age

Modern anaesthesia and postoperative critical care facilities have allowed major head and neck surgery to be carried out on patients with significant medical comorbidity. Advancing age is now not considered to be a contraindication to major head and neck cancer surgery. Conversely, young patients should not be denied radiotherapy for fear of inducing a second malignancy, e.g. sarcoma, in later life.

Previous radiotherapy

A second course of radiotherapy to a previously irradiated site is contraindicated as the tumour is likely to be radioresistant and reirradiation will invariably result in extensive tissue necrosis.

Field change

Surgery is preferred when multiple tumours are present or there is extensive premalignant change of the oropharyngeal mucosa. Radiotherapy is unsatisfactory as the entire oral cavity requires treatment, causing severe morbidity. In addition, subsequent postradiotherapy changes make the diagnosis of future premalignancy and malignancy more difficult.

Management of premalignant conditions

Elimination of associated aetiological factors is the basis of the management of premalignant oral mucosal lesions. Cessation of smoking, elimination of the areca nut/pan habit and reduction

in alcohol consumption should be encouraged in all patients with premalignant lesions. A photographic record of the lesion is useful, particularly for long-term follow up. All erythroplakia and speckled leukoplakia should undergo urgent incisional biopsy. Biopsy from more than one site provides a better representation of histological changes within a lesion.

Severe epithelial dysplasia and carcinoma *in situ* should be ablated by surgical excision or laser vaporisation. Small lesions, particularly on the lateral border of the tongue or buccal mucosa, may be managed with surgical excision and primary closure by undermining the adjacent mucosa. Larger defects can be managed with laser vaporisation and allowed to epithelialise spontaneously (Figure 49.11). With mild-to-moderate epithelial dysplasia, treatment is facilitated by elimination of causative agents. Patients who continue to smoke should be managed as for severe dysplasia and carcinoma *in situ*. Patients who cease smoking and areca nut/pan habits may be followed up closely at three-monthly intervals.

LIP CANCER

Surgery and external beam radiotherapy are highly effective methods of treatment for lip cancer. The cure rate approaches 90 per cent for either modality.

Premalignant changes on the lower lip mucosa are frequently extensive and are best managed by a lower lip shave, in which

Figure 49.11 (a) Leukoplakia with severe dysplasia of the lateral border of the tongue. (b) Laser vaporisation.

the vermilion defect is closed by advancement of the lower labial mucosa.

Small tumours

Small tumours (<2 cm) of the lip can be managed with either a V- or W-shaped excision under local or general anaesthesia. The defect, which should be no larger than one-third of the total lip size, is closed in three layers – mucosa, muscle and skin – with particular attention paid to the correct alignment of the vermilion border (Figure 49.12).

Intermediate tumours

Larger tumours, which produce defects of between one-third and two-thirds the size of the lower lip, require local flaps for reconstruction. V or W excision will result in microstomia. Large central defects are best managed using the Johansen step technique (Figure 49.13). This allows closure of the defect by symmetrical advancement of soft-tissue flaps, utilising the excess skin in the labiomental grooves. Alternative techniques include the Bernard rotational flap.

Total lip reconstruction

Extensive tumours of the lower lip, which invade adjacent tissues (T4), have a high incidence of neck node metastasis. Patients with such advanced disease require surgery that may include unilateral or bilateral selective neck dissection and total excision of the lower lip and chin. The lower lip defect is best reconstructed with a forearm flap suspended with palmaris longus tendon (Figure 49.14).

TONGUE CANCER

Up to 30 per cent of patients with a T1 (<2 cm diameter) tumour (Figure 49.15) have occult metastasis at presentation and should undergo simultaneous treatment of the neck by

either selective neck dissection or radiotherapy. When performing surgical excision of the primary tumour, a 2-cm margin in all planes should be achieved to ensure a wide, complete excision. Resection resulting in partial or hemiglossectomy can be performed with either a cutting diathermy or laser if available. Advanced tumours (T3 and T4) often encroach upon the floor of the mouth and, occasionally, the mandible. In these circumstances, a major resection of the tongue and floor of the mouth and mandible is required. T4 tumours of the oral tongue often cross the midline, for which total glossectomy is the only option to achieve adequate tumour clearance.

When a patient undergoes simultaneous neck dissection, the resection of the primary tumour should preferably be in continuity with the neck node specimen. This eliminates 'lingual' lymph nodes (lying between the primary tumour and submandibular (level I) nodes); these nodes may contain micro-deposits of tumour, which may lead to local recurrence.

Access

Access for oropharyngeal cancer is important to allow accurate assessment and clear visualisation to enable tumour clearance to be achieved. Access techniques include:

- transoral – small anterior oral tumours only;
- lip-split technique and paramedian or median mandibulotomy (Figure 49.16);
- visor incision (Figure 49.17).

Reconstruction

Small defects of the lateral tongue can be managed by primary closure or allowed to heal by secondary intention. Larger defects, e.g. T2, T3 and T4 resections, require formal reconstruction to encourage good speech and swallowing. A radial forearm flap either with skin (Figure 49.18) and/or fascia, utilising microvascular anastomosis, gives a good functional

Figure 49.12 (a) Skin markings for wedge excision of the lower lip. (b) Primary closure.

Figure 49.13 (a) Skin markings for Johansen step reconstruction. (b) Closure of lip and labiomental steps.

Figure 49.14 (a) Skin markings for total excision of the lower lip, chin and left selective neck dissection. (b) Postoperative view of the reconstructed lower lip using a radial artery forearm flap.

result. Large-volume defects, including total glossectomy, require more bulky flaps such as the rectus abdominus free flap. If feasible, the preservation of one or both hypoglossal nerves is useful to encourage floor of mouth function to help relearn swallowing.

FLOOR OF MOUTH

Carcinoma of the floor of the mouth can spread to the ventral surface of the anterior tongue or encroach upon the lower anterior alveolus (Figure 49.19). Surgical excision may include a partial anterior glossectomy and anterior mandibular resection. Only very small tumours of the floor of mouth can be managed by simple excision. The visor procedure provides excellent access (see Figure 49.17).

Figure 49.17 Visor approach to the anterior mandible/floor of the mouth and tongue.

Figure 49.18 Radial artery forearm flap raised before division of vascular pedicle and cephalic vein (arrow).

Reconstruction

Small tumours of the floor of the mouth frequently require formal reconstruction. It is unacceptable to advance the cut surface of the ventral tongue to the labial mucosa as severe difficulties with speech, swallowing and mastication ensue. Simple soft-tissue defects of the anterior floor of mouth are best reconstructed with a radial artery forearm flap. If a patient

Figure 49.19 Spread of tumour from the anterior floor of the mouth showing the different patterns in a dentate (left) and edentulous (right) mandible.

is unfit for microvascular free flap surgery or the facilities are limited, bilateral nasolabial flaps tunnelled into the mouth and interdigitated provide an acceptable alternative (Figure 49.20). Three weeks later their pedicles are divided and inset into the lateral floor of mouth defects. Large defects that involve rim resection of the anterior mandible may also be managed with soft tissue reconstruction only. Full-thickness resection of the anterior mandible, however, requires immediate reconstruction to prevent severe functional defects or a cosmetic deformity. Vascularised bone with a soft-tissue component provides the most up-to-date method of reconstruction. A fibula flap or a vascularised iliac crest graft (deep circumflex iliac artery (DCIA)) are two options in the management of anterior mandible defects with simultaneous floor of mouth defects.

BUCCAL MUCOSA

Squamous cell carcinoma of the buccal mucosa (Figure 49.21) should be excised widely, including the underlying buccinator muscle. Larger tumours occasionally extend onto the maxillary tuberosity, tonsillar fossa or mandibular alveolus. Facial skin involvement is rare but carries a poor prognosis. Although cervical node metastasis from buccal mucosa usually occurs less readily than in tongue and floor of mouth cancer, a simultaneous ipsilateral selective supraomohyoid neck dissection (levels I, II, III) is considered good practice.

Access for buccal carcinoma can be achieved either transorally for smaller lesions (T1, T2) or using the lip-splitting technique for larger lesions (T3, T4).

Reconstruction of the buccal mucosa prevents scarring and trismus. Options include the radial artery forearm flap or a temporalis muscle flap. Raw temporalis muscle inset into the buccal mucosal defect will epithelialise spontaneously over several weeks.

LOWER ALVEOLUS

Surgery is the treatment of choice for tumours that involve the mandibular alveolus (Figure 49.22a). Ipsilateral selective neck dissections should be performed for lateral tumours although the incidence of occult neck node metastasis is low. Bilateral selective neck dissection should be considered for anterior tumours. Bone invasion (Figure 49.22b) demands segmental resection

Figure 49.20 (a) Skin markings for bilateral nasolabial flaps. (b) Transposition of bilateral nasolabial flaps into the anterior floor of the mouth.

of the mandible in continuity with neck dissection. Primary or immediate reconstruction is preferred as the functional and cosmetic outcomes are usually superior to those of delayed reconstruction. Options for bony reconstruction are shown in Table 49.2. They include the fibula flap for the edentulous mandible (Figure 49.22c and d) and the iliac crest (DCIA) for patients with a dentate mandible (Figure 49.23). The vascularised iliac crest can be wrapped with internal oblique abdominal wall muscle, which epithelialises spontaneously. This intraoral epithelialisation provides an excellent surface for prosthetic replacement.

Although non-vascularised bone grafts have a place in mandibular reconstruction, the long-term success is frequently low as many patients receive postoperative radiotherapy, which results in the loss of the bone and dehiscence of the titanium tray or reconstruction plate.

Figure 49.21 Exophytic squamous cell carcinoma of the right buccal mucosa.

Table 49.2 Mandibular reconstruction.

Method	Technique
No reconstruction	Primary closure
Soft tissue only	Pectoralis major myocutaneous flap
Alloplastic material	2.4 mm reconstruction plate alone
Combination alloplastic/soft tissue	2.4 mm reconstruction plate and pectoralis major flap
Non-vascularised bone grafts	Titanium tray and cancellous chips (iliac crest)
Vascularised bone grafts	Fibula (edentulous and dentate); iliac crest (dentate); scapula (concomitant large soft-tissue defect)

Figure 49.22 (a) Extensive squamous cell carcinoma of the anterior mandible involving the floor of the mouth. (b) Plain radiography (orthopantomogram) revealing bony destruction of the anterior mandible. (c) Osseocutaneous fibula flap. (d) Postoperative radiograph of the reconstructed mandible with fibula flap and reconstruction plate.

RETROMOLAR PAD

Tumours at this site frequently, but not always, invade the ascending ramus of the mandible. They also spread medially into the soft palate or even the tonsillar fossa. Access for excision is carried out via a lip split and mandibulotomy (see Figure 49.16). Small defects are managed either with a temporalis muscle flap or a radial artery forearm flap. Segmental mandibular resections require vascularised bone to achieve adequate reconstruction.

HARD PALATE AND MAXILLARY ALVEOLUS

The maxillary alveolus and hard palate are relatively uncommon sites for SCC. A tumour arising in these areas may arise either from the oral mucosa per se or from the maxillary antrum penetrating the oral cavity. In the Indian subcontinent, carcinoma of the hard palate is common and particularly associated with reverse smoking. Occasionally, malignant tumours of minor salivary glands present as swellings of the hard palate. Small tumours of the maxillary alveolus can be managed by transoral partial maxillectomy. More extensive tumours involving the

floor of the maxillary sinus require wider access by a Weber–Ferguson incision (Figure 49.24). If the preoperative investigations demonstrate extension of the disease into the pterygoid space or the infratemporal fossa, the prognosis is poor as surgical clearance is difficult if not impossible. Tumour extending into the orbit requires simultaneous orbital exenteration or even a combined neurosurgical resection. The vascularised iliac crest graft is the method of choice for immediate maxillary reconstruction although the fibula provides adequate bony replacement to maintain facial contour.

Microvascular free tissue transfer remains the method of choice for the management of defects in the oropharynx (Table 49.3). Free flaps are superior reconstructive options to pedicled or local flaps, which may be used for salvage procedures or recurrent disease. Each ‘free’ flap has a principal blood supply and a concomitant venous drainage. The flaps can be tailored to the defect to include skin, fascia, bone and muscle. The techniques of free tissue transfer demand specialist training and a microscope to connect blood vessels in the neck after neck dissection, e.g. facial artery to the prepared artery attached to the flap. The vascular anatomy of microvascular free flaps is summarised in Table 49.4.

Table 49.3 Primary reconstructive options in oropharyngeal cancer.

Anatomical site	Microvascular free flap	Alternative flaps
Floor of mouth	Forearm	Nasolabial flaps (bilateral)
Lateral tongue	Forearm	Platysma skin flap
Total tongue/glossectomy	Rectus abdominus	Pectoralis major/lateral thigh
Buccal mucosa	Forearm	Temporalis muscle
Mandible		
Dentate	Iliac crest	Fibula
Edentulous	Fibula	Reconstruction plate and pectoralis major
Maxilla		
Low-level/hard palate	Temporalis muscle	Forearm
High	Iliac crest	Fibula
Soft palate/tonsil	Forearm	Temporalis muscle, galeal flap, pectoralis major
Tongue base	Forearm	Pectoralis major

Table 49.4 Microvascular ‘free’ flaps in oropharyngeal reconstruction.

Flap	Blood supply	Common variants
Forearm	Radial artery	Skin only; fascia only
Composite forearm	Radial artery	Skin and bone (radius)
Anterolateral thigh	Perforator vessels of the profunda femoris artery	Skin only; skin and muscle
Rectus abdominus	Deep inferior epigastric artery	Skin and muscle; muscle only
Fibula	Peroneal artery	Bone and skin; bone only; bone and fascia/fat
Ilium	Deep circumflex iliac artery	Bone only; bone and muscle; bone, muscle and skin
Scapula	Subscapular artery	Bone and skin; bone and muscle

Figure 49.24 Weber-Ferguson incision for maxillectomy (lower eyelid extension is rarely required).

OROPHARYNX

Tumours of the oropharynx are frequently not amenable to surgery because of the morbid nature of the resection – small and intermediate (T1, T2) tongue base tumours may necessitate total glossectomy to achieve adequate clearance at the root of the tongue. Tumours of the soft palate and tonsil, however, can be managed with either primary surgery in continuity with neck dissection or primary radiotherapy. Subsequent defects of the tonsillar area can be managed with a forearm flap. Defects of the soft palate, including total soft palate reconstruction, are best managed with a combined reconstruction consisting of a superiorly based pharyngeal flap to line the nasal surface and a forearm flap for the oral surface of the new soft palate. Chemoradiotherapy is now increasingly used to manage tumours of the oropharynx in which organ preservation, but not necessarily function, is the goal. In patients with large-volume neck disease, e.g. N2 and N3, a combined modality of neck dissection followed by chemoradiotherapy to manage the tumour at the primary site and residual neck disease is gaining popularity.

Chemotherapy

The role of chemotherapy has evolved over the last 20–30 years. It was initially reserved for treatment of recurrent and incurable disease, often using single-agent therapy. Combination chemotherapy, particularly platinum agents and 5-fluorouracil, is now more effective in controlling recurrent and incurable disease. However, combination chemotherapy is associated with more severe side effects and a balance needs to be reached between efficacy, palliation and quality of life.

Chemotherapy also now has an important role in the treatment of locally advanced and previously untreated oropharyngeal carcinoma. There is compelling evidence that tumours of the tongue base may best be managed with primary chemoradiotherapy rather than radical surgery. The addition of chemotherapy with radiotherapy does, however, increase the morbidity and mortality rates. Patients who are frail or who have significant medical comorbidity may not tolerate the regime.

Chemoradiotherapy has been shown to improve survival in patients whose tumours are deemed unresectable, although organ preservation, i.e. swallowing and speech, is not always sustained. There is good evidence for the superiority of chemoradiotherapy over radiotherapy alone; however, chemoradiotherapy is rarely effective in large-volume disease.

Management of the neck

The management of the cervical lymph nodes is highly dependent on the planned treatment of the primary tumour. When surgery is deemed appropriate for the primary tumour, simultaneous neck dissection should be considered. If radiotherapy is preferred, treatment to the neck should be contemplated, particularly when there is a high risk of occult metastases, e.g. tongue.

The clinically node-negative neck

The cervical lymph nodes contain occult metastases in up to 30 per cent of patients. This is particularly significant with patients presenting with primary carcinomas of the tongue and, to a lesser extent, floor of mouth. Tumours arising in the buccal mucosa and mandibular alveolus are less likely to have occult metastasis. Nevertheless, increasing evidence exists that active treatment of cervical lymph nodes in the absence of obvious disease is considered good practice. Patients with carcinoma of the lateral tongue, floor of mouth and mandibular alveolus are best managed by supraomohyoid neck dissection (surgical removal of lymph node levels I, II and III in continuity with the primary tumour) (Figure 49.25).

Good evidence exists that carcinoma of the tongue can produce occult cervical metastasis directly to lymph node level IV. Consequently, the extended supraomohyoid neck dissection removing lymph node levels I, II, III and IV is indicated for patients with carcinoma of the tongue with N0 neck disease. Selective neck dissection is regarded as a staging as much as a therapeutic procedure. Patients who have two or more positive nodes or evidence of extracapsular spread should be managed with postoperative radiotherapy to the neck and the primary site.

Elective external beam radiotherapy is an alternative when radiotherapy is planned for the primary site.

The clinically node-positive neck

The presence of an isolated ipsilateral cytologically positive lymph node of <3 cm is now considered best managed by selective supraomohyoid neck dissection. There is good evidence that radical or modified radical neck dissection is not required for patients with N1 neck disease associated with oropharyngeal cancer.

N2a and N2b disease

Radical or modified radical neck dissection (Figure 49.26), often followed by postoperative radiotherapy, is appropriate to control neck disease. Patients unfit for surgery can be offered external beam radiotherapy palliation.

N2c disease

Patients with mouth cancer presenting with bilateral nodes often have a large, inoperable, primary tumour. Bilateral neck dissection can be undertaken, although morbidity is high. One internal jugular vein needs to be spared, usually on the side that is less involved with disease. Postoperative radiotherapy is indicated if there is multiple node involvement or extracapsular spread. Postoperative neck oedema and facial congestion occurs and may take months to resolve.

N3 disease

In N3 disease, there is extensive involvement of the neck, often with fixation to the overlying skin. This is associated with advanced primary disease. Radical neck dissection may be feasible in such circumstances, but strong consideration should be given to radiotherapy if there is evidence of tumour involving the internal carotid artery or the skull base.

The different types of neck dissection and their indications are summarised in Table 49.5.

Table 49.5 Neck dissection in oropharyngeal cancer.

Type of neck dissection	Lymph node levels removed	Indication
Selective		
Supraomohyoid	I–III	N0; N1; neck access for microsurgery
Extended supraomohyoid neck dissection	I–IV	Oral tongue cancer with N0 neck nodes; N1
Radical		
Full	I–V	N2; N3; neck recurrence after radiotherapy
Modified radical neck dissection	I–V, with preservation of internal jugular vein, accessory nerve and/or sternomastoid muscle	Involvement of neck skin; recurrence after selective neck dissection

Figure 49.25 (a) Anatomical boundaries for supraomohyoid neck dissection (levels I, II, III). (b) Standard skin incision for neck dissection (solid line). (c) Deep cervical lymph nodes (box) posterolateral to the internal jugular vein (arrow). (d) Completed supraomohyoid neck dissection revealing great vessels of the neck (arrow).

COMPLICATIONS

Notwithstanding the general complications of major surgery, complications specifically associated with the treatment of oropharyngeal cancer are speech deficiencies, especially with resection of the anterior floor of the mouth and tongue; swallowing dysfunction and aspiration, especially after oropharyngeal resection; neurological injury, e.g. lingual nerve, hypoglossal nerve palsy; wound breakdown and cervical fistula formation; failure of internal fixation/reconstruction plates; failure of microvascular anastomosis; and flap failure. Other complications that may occur are listed in Summary box 49.5.

Patients undergoing treatment for oropharyngeal cancer frequently develop severe functional problems. The size and location of the tumour will dictate the extent of resection and the sacrifice of important structures.

Loss of tongue and floor of mouth musculature and the removal of bone and associated muscle attachments together

Summary box 49.5

Complications of treatment for oropharyngeal cancer

Surgical

- Accessory nerve palsy – shoulder dysfunction and pain
- Soft-tissue oedema, especially bilateral neck dissection
- Phrenic nerve injury
- Thoracic duct injury
- Cranial nerve injury
- Rupture of the carotid artery

Radiotherapy

- Osteoradionecrosis of the mandible
- Hypothyroidism
- Atherosclerosis of the carotid artery
- Neck and shoulder dysfunction
- Trismus
- Xerostomia
- Visual impairment
- Radiation neuritis

Chemotherapy

- Nausea and vomiting
- Diarrhoea
- Stomatitis
- Gastrointestinal upset
- Renal toxicity
- Leukopenia and thrombocytopenia

with the sacrifice of sensory and motor cranial nerves all greatly affect not only appearance but also speech, swallowing and nutritional status. Psychological disturbance is universal in patients undergoing major head and neck cancer surgery and radiotherapy.

The techniques of immediate reconstruction, particularly with microvascular flaps, minimise the complications and side effects but many patients are, nevertheless, radically changed for the remainder of their lives. Patients undergoing 'salvage' surgery following primary radiotherapy frequently undergo delayed wound healing, cervical fistula formation and, occasionally, carotid artery blowout/rupture. Skin anaesthesia associated with scar contracture creates additional problems, particularly with neck mobility and trismus.

POST-TREATMENT MANAGEMENT

Patients with oropharyngeal cancer need to be followed up regularly, not only to detect possible recurrence but also to manage the morbidity associated with treatment. In total, 70 per cent of recurrences occur in the first 12 months following treatment and 90 per cent in the first two years. Patients who survive for five years are cured and discharged. Recurrence after extensive surgery and radiotherapy is frequently beyond any further treatment and palliative care is a logical pathway.

OUTCOME AND PROGNOSIS

Survival after oropharyngeal cancer is directly related to:

- the size of the primary tumour (T stage);
- the evidence of neck node metastasis (N stage);
- concomitant medical problems, e.g. cardiorespiratory disease.

Patients with large primary tumours are more likely to develop cervical node metastasis. Cervical node metastasis, particularly with extracapsular spread, is the most significant factor in determining prognosis for oropharyngeal cancer. The overall five-year survival rates are shown in Table 49.6.

Supportive treatment is important for patients with oropharyngeal cancer, particularly in the form of speech and language support and dietetic and psychological input. Smoking cessation and a drastic reduction in alcohol intake reduces the risk of developing further metachronous carcinomas in the aerodigestive tract.

Table 49.6 Five-year survival rates for oropharyngeal cancer.

Stage at presentation	Survival rate (%)
I	80–90
II	65–75
III	40–50
IV	30

LEARNING OBJECTIVES

To understand:

- The surgical anatomy of the salivary glands
- The presentation, pathology and investigation of salivary gland disease
- The medical and surgical treatment of stones, infections and tumours that affect salivary glands

INTRODUCTION

There are four main salivary glands, two submandibular glands and two parotid glands. In addition, there are multiple minor salivary glands.

MINOR SALIVARY GLANDS

Anatomy

The mucosa of the oral cavity contains approximately 450 minor salivary glands. They are distributed in the mucosa of the lips, cheeks, palate, floor of the mouth and retromolar area. These minor salivary glands also appear in other areas of the upper aerodigestive tract including the oropharynx, larynx and trachea as well as the sinuses. They have a histological structure similar to that of mucous-secreting major salivary glands. Overall, they contribute to 10 per cent of the total salivary volume (Summary box 50.1).

Summary box 50.1

Anatomy of salivary glands

- Two submandibular glands
- Two parotid glands
- Two sublingual glands
- Approximately 450 minor salivary glands

Common disorders of minor salivary glands

Cysts

Extravasation cysts are common and result from trauma to the overlying mucosa. They usually affect minor salivary glands within the lower lip, producing a variable swelling that is painless and usually, but not always, translucent (Figure 50.1). Some resolve spontaneously, but most require formal surgical excision that includes the overlying mucosa and the underlying minor salivary gland. Recurrence is rare.

Figure 50.1 Mucous retention cyst. A translucent swelling on the lower lip is typical.

Tumours

Few tumours show more diversity in histological appearance and anatomical site than those that arise from mucous glands of the upper aerodigestive tract. Tumours of minor salivary glands are histologically similar to those of major glands; however, up to 90 per cent of minor salivary gland tumours are malignant. Although tumours of minor salivary gland origin occur anywhere in the upper aerodigestive tract, common sites for tumour formation include the upper lip, palate and retromolar regions. Less common sites for minor salivary gland tumours include the nasal and pharyngeal cavities. Minor salivary gland tumours have also been reported in the paranasal sinuses and throughout the pharynx. These tumours arise in submucosal seromucous glands that are found throughout the upper aerodigestive tract. Very rarely, a mucoepidermoid carcinoma can present as an intraosseous tumour of the mandible.

Benign minor salivary gland tumours present as painless, firm, slow-growing swellings. Overlying ulceration is extremely rare. Minor salivary gland tumours of the upper lip are managed by excision to include the overlying mucosa, with primary closure (Figure 50.2a–c).

Benign tumours of the palate, less than 1 cm in diameter, can be managed by excisional biopsy, and the defect is allowed to heal by secondary intention (Figure 50.3a–d). Where tumours of

Figure 50.2 (a) Pleomorphic adenoma of the upper lip. (b) Tumour excised with overlying mucosa. (c) Primary closure of the defect.

the palate are greater than 1 cm in diameter, incisional biopsy is recommended to establish a diagnosis prior to formal excision.

Malignant minor salivary gland tumours are rare. They have a firm consistency, and the overlying mucosa may have a varied discolouration from pink to blue or black (Figure 50.4). The tumour may become necrotic with ulceration as a late presentation.

Malignant minor salivary gland tumours of the palate are managed by wide excision which may involve partial or total maxillectomy. The subsequent defect can be managed by either prosthetic obturation or immediate reconstruction. Various microvascular flaps have been designed to reconstruct maxillectomy defects, including radial forearm flap, fibular flap, rectus abdominus, latissimus dorsi and the vascularised iliac crest graft (Figure 50.5a and b).

THE SUBLINGUAL GLANDS

Anatomy

The sublingual glands are a paired set of minor salivary glands lying in the anterior part of the floor of mouth between the mucous membrane, the mylohyoid muscle and the body of the mandible close to the mental symphysis. Each gland has numerous excretory ducts that open either directly into the oral cavity

Figure 50.3 (a) Pleomorphic adenoma in the right palate in a 12-year-old girl. (b) Tumour marked out with adequate margins including the overlying mucosa. (c) The subsequent defect. (d) Healing by secondary intention three years after surgery.

or indirectly via ducts that drain into the submandibular duct (Summary box 50.2).

Summary box 50.2

Sublingual glands

- Problems are rare
- Minor mucous retention cysts may need surgery
- Plunging ranula is a retention cyst that tunnels deep
- Nearly all tumours are malignant

Figure 50.4 Adenoid cystic carcinoma of the left maxillary alveolus.

Figure 50.6 Large ranula affecting the floor of the mouth.

Figure 50.5 (a) Postoperative appearance following left maxillectomy and immediate reconstruction with a vascularised iliac crest graft and abdominal wall musculature (epithelialised). (b) Postoperative radiographic appearance of a reconstructed left maxilla with internal fixation.

Common disorders of the sublingual glands

Cysts

Minor mucous retention cysts develop in the floor of the mouth either from an obstructed minor salivary gland or from the sublingual salivary gland. The term 'ranula' should be applied only to a mucous extravasation cyst that arises from a sublingual gland. It produces a characteristic translucent swelling that takes on the appearance of a 'frog's belly' (ranula) (Figure 50.6). A ranula can resolve spontaneously, but many also require formal surgical excision of the cyst and the affected sublingual gland. Incision and drainage, however tempting, usually results in recurrence.

Plunging ranula

Plunging ranula is a rare form of mucous retention cyst that can arise from both sublingual and submandibular salivary glands. Mucus collects within the cyst, which perforates through the mylohyoid muscle diaphragm to enter the neck. Patients present with a dumb-bell-shaped swelling that is soft, fluctuant and painless in the submandibular or submental region of the neck (Figure 50.7a and b). Diagnosis is made on ultrasound or magnetic resonance imaging (MRI) examination. Excision is usually performed via a cervical approach removing the cyst and both the submandibular and sublingual glands. Smaller plunging ranulas can be treated successfully by transoral sublingual gland excision, with or without marsupialisation.

Tumours

Tumours involving the sublingual gland are extremely rare and are usually (85 per cent) malignant. They present as a hard or firm painless swelling in the floor of the mouth. Treatment requires wide excision involving the overlying mucosa and simultaneous neck dissection. Immediate reconstruction of the intraoral defect is recommended using, for example, a radial artery forearm flap.

Figure 50.7 Plunging ranula in the left submandibular region.

Ranula is derived from 'rana', the Latin for frog.

Thomas Wharton, 1616–1673, physician, St Thomas's Hospital, London, UK, described the submandibular duct in 1656.

THE SUBMANDIBULAR GLANDS

Anatomy

The submandibular glands are paired salivary glands that lie below the mandible on either side. They consist of a larger superficial and a smaller deep lobe that are continuous around the posterior border of the mylohyoid muscle. Important anatomical relations include the anterior facial vein running over the surface of the gland and the facial artery. The deep part of the gland lies on the hyoglossus muscle closely related to the lingual nerve and inferior to the hypoglossal nerve. The gland is surrounded by a well-defined capsule that is derived from the deep cervical fascia which splits to enclose it. The gland is drained by a single submandibular duct (Wharton's duct) that emerges from its deep surface and runs in the space between the hyoglossus and mylohyoid muscles. It drains into the anterior floor of the mouth at the sublingual papilla. There are several lymph nodes immediately adjacent and sometimes within the superficial part of the gland (Summary box 50.3).

Summary box 50.3

Important anatomical relationships of the submandibular glands

- Lingual nerve
- Hypoglossal nerve
- Anterior facial vein
- Facial artery
- Marginal mandibular branch of the facial nerve

Ectopic/aberrant salivary gland tissue

The most common ectopic salivary tissue is the Stafne bone cyst. This presents as an asymptomatic, clearly demarcated radiolucency of the angle of the mandible, characteristically below the inferior dental neurovascular bundle (Figure 50.8). It is formed by invagination into the bone on the lingual aspect of the mandible of an ectopic lobe of the juxtaposed submandibular gland. No treatment is required.

Inflammatory disorders of the submandibular gland

Inflammation of the submandibular gland is termed sialadenitis. Submandibular sialadenitis may be acute, chronic or acute on chronic.

Figure 50.8 Plain radiographic appearance of a Stafne bone cyst.

Common causes are:

- Acute submandibular sialadenitis:
 - **Viral.** The paramyxovirus (mumps) is a viral illness of the salivary glands that usually produces parotitis. The submandibular glands are occasionally involved, causing painful tender swollen glands. Other viral infections of the submandibular gland are extremely rare.
 - **Bacterial.** Bacterial sialadenitis is more common than viral sialadenitis and occurs secondary to obstruction. Following infection and despite control of acute symptoms with antibiotics, the gland frequently becomes chronically inflamed and requires formal excision.
- Chronic submandibular sialadenitis.

Obstruction and trauma

The most common cause of obstruction within the submandibular gland is stone formation (sialolithiasis) within the gland and its associated duct system. Eighty per cent of all salivary stones occur in the submandibular glands because their secretions are highly viscous. Eighty per cent of submandibular stones are radio-opaque and can be identified on plain radiography (Figure 50.9).

Clinical symptoms

Patients usually present with acute painful swelling in the region of the submandibular gland, precipitated by eating (Figure 50.10). The swelling occurs rapidly and often resolves spontaneously over 1–2 hours after the meal is completed. This classical picture occurs when the stone causes complete obstruction, usually at the opening of the submandibular duct. More frequently, the stone causes only partial obstruction when it lies within the hilum of the gland or within the duct in the floor of the mouth. In such circumstances, symptoms are more infrequent, producing minimal discomfort and swelling, not confined to mealtimes. Clinical examination reveals an enlarged firm submandibular gland, tender on bimanual examination. Pus may

Figure 50.9 Lower occlusal x-ray highlighting a radio-opaque submandibular duct stone (arrowhead). Note the larger stone posteriorly located in the hilum of the gland (arrow).

Figure 50.10 Acute left submandibular sialadenitis.

be visible, draining from the sublingual papilla (Figure 50.11), the consequence of chronic and non-specific bacterial infection.

Management

If the stone is lying within the submandibular duct in the floor of the mouth anterior to the point at which the duct crosses the lingual nerve (second molar region), the stone can be removed by incising longitudinally over the duct. Once the stone has been delivered, the wall of the duct should be left open to promote free drainage of saliva. Suturing the duct will lead to stricture formation and the recurrence of obstructive symptoms. Where the stone is proximal to the lingual nerve, i.e. at the hilum of the gland, stone retrieval via an intraoral approach should be avoided as there is a high risk of damage to the lingual nerve during exploration in the posterior lingual gutter. Treatment is by simultaneous submandibular gland excision and removal of the stone and ligation of the submandibular duct under direct vision. The retrieval of stone via an endoscopic approach, and/or removal by lithotripsy is gaining favour in some centres, but specialist equipment including a sialadenoscope is required.

Other causes of submandibular duct obstruction include external pressure, particularly trauma to the floor of the mouth from an overextended flange on a lower denture which impinges on the sublingual papilla causing inflammation and subsequent stricture.

Submandibular gland excision

Submandibular gland excision is indicated for:

- sialadenitis
- salivary tumours.

Figure 50.11 Acute suppurative submandibular sialadenitis. There is pus extruding from the left sublingual papilla.

Excision of the submandibular gland involves four distinct phases.

Incision and exposure of gland

Surgery is usually performed under endotracheal general anaesthesia with moderate neck extension and the chin rotated to the opposite side. The incision should be marked at least 3–4 cm below the lower border of the mandible to avoid damage to the marginal mandibular branch of the facial nerve (Figure 50.12a). The incision should be sited within the nearest skin crease and should be no more than 6 cm long. Infiltration with lidocaine with adrenaline is optional. Sharp dissection is performed down to the platysma muscle, which should be clearly identified to facilitate later closure (Figure 50.12b). The muscle is incised and then retracted. The underlying investing layer of deep cervical fascia is then divided, and the marginal mandibular branch of the facial nerve that normally runs on the deep surface of the platysma muscle is preserved. Posteriorly, the incision approaches the angular tract where the deep cervical fascia splits to form the investing layer around the sternomastoid muscle. Superficial veins, including the anterior facial vein, require ligation.

Gland mobilisation

Deepening the incision divides the submandibular gland capsule. In inflammatory conditions, the submandibular gland is excised by intracapsular dissection, mobilising the gland by sharp dissection. For tumours of the submandibular gland, extracapsular dissection by suprahyoid neck dissection is performed.

The superficial lobe of the submandibular gland is first mobilised by retracting superiorly with an Allis forceps. As dissection proceeds, the posterior belly and anterior belly of the digastric muscle are identified. Dissection posteriorly identifies the facial artery (Figure 50.13), which is divided to facilitate further mobilisation. The course of the facial artery is variable, sometimes penetrating the gland emerging on the upper border, and

Figure 50.12 (a) Surface landmarks of submandibular gland excision. (b) Skin flaps elevated and platysma exposed.

Figure 50.13 Submandibular gland mobilisation and exposure of the facial artery.

sometimes lying in a groove on the deeper aspect of the gland. The gland is further mobilised by blunt and sharp dissection. A number of small arteries and veins are encountered, which require control with bipolar diathermy.

Dissection of the deep lobe and identification of the lingual nerve

An important landmark in submandibular gland dissection is the posterior border of the mylohyoid muscle. Once identified, it can be retracted forwards to reveal the deep lobe of the gland. Several veins are usually encountered, which need to be controlled with diathermy. The gland is then retracted inferiorly, invariably attached to the lingual nerve through parasympathetic secretor motor fibres. In the presence of chronic infection and subsequent fibrosis, identification of the lingual nerve on the deep aspect of the gland is sometimes difficult. It is imperative that the lingual nerve is formally identified prior to division of the parasympathetic fibres. The gland is then pedicled entirely on the submandibular duct, which, once identified, is ligated. The gland is delivered and sent for histological examination. The hypoglossal nerves lie deep to the submandibular capsule and should not be damaged during intracapsular dissection (Figure 50.14).

Three cranial nerves are at risk during removal of the submandibular gland:

- 1 the marginal mandibular branch of the facial nerve
- 2 the lingual nerve
- 3 the hypoglossal nerve.

An adequate incision coupled with meticulous haemostasis allows the surgeon to identify these important structures during surgery.

Figure 50.14 Bed of the submandibular triangle following submandibular gland removal, revealing the posterior edge of the mylohyoid muscle and the tendon of the digastric muscle.

Wound closure

Haemostasis is confirmed and a vacuum suction drain inserted. The wound is closed using a continuous resorbable suture to the platysma muscle, as the platysma muscle has a direct contribution to the depressor activity of the corner of the mouth. The skin may be closed with a subcuticular non-resorbable suture, removed 7 days after surgery. The drain remains for 24 hours.

Complications of submandibular gland excision

Complications are:

- haematoma
- wound infection
- marginal mandibular nerve injury
- lingual nerve injury
- hypoglossal nerve injury
- transection of the nerve to the mylohyoid muscle producing submental skin anaesthesia.

Tumours of the submandibular gland

Tumours of the submandibular gland are uncommon and usually present as a slow-growing, painless swelling within the submandibular triangle (Figure 50.15). Only 50 per cent of submandibular gland tumours are benign, in contrast to 80–90 per cent of parotid gland tumours (Table 50.1). In many circumstances, the swelling cannot, on clinical examination, be differentiated from submandibular lymphadenopathy. Most salivary neoplasms, even malignant tumours, are often slow-growing, painless swellings. Unfortunately, pain is not a reliable indication of malignancy as benign tumours often present with pain in the affected gland, presumably due to capsular distension or outflow obstruction.

Table 50.1 Salivary gland tumours – frequency and distribution.

Type	Location	Frequency	Malignant (%)
Major	Parotid	Common	10–20
	Submandibular	Uncommon	50
	Sublingual	Very rare	85
Minor	Upper aerodigestive tract	Rare	90

Clinical features of malignant salivary tumours

These include:

- facial nerve weakness
- rapid enlargement of the swelling
- induration and/or ulceration of the overlying skin
- cervical node enlargement.

Figure 50.15 Benign tumour of the right submandibular gland.

Investigation

Computed tomography (CT) and MRI scanning are the most helpful techniques for imaging tumours arising in the major salivary glands. The tumour is intrinsic to the gland, and its border can be imaged to highlight whether it is circumscribed and probably benign, or diffuse, invasive and probably malignant. The scan will highlight the relationship of the tumour to other anatomical structures, which is helpful in planning surgery.

Open surgical biopsy is contraindicated as this may seed the tumour into surrounding tissues, making it impossible to eradicate microscopic deposits of tumour cells.

Fine-needle aspiration biopsy is a safe alternative to open biopsy. There is evidence to suggest that, provided the needle gauge does not exceed 18G, there is no risk of seeding viable tumour cells. The role of fine-needle aspiration biopsy is, however, controversial as it rarely alters surgical management.

Management of submandibular gland tumours

As with all salivary gland tumours, surgical excision with a cuff of normal tissue is the goal. When the tumour is small and entirely encased within the submandibular gland parenchyma, straightforward intracapsular submandibular gland excision is appropriate. However, benign tumours that are large and project beyond the submandibular gland are best served by suprahyoid neck dissection, preserving the marginal mandibular branch of the facial nerve, lingual nerve and hypoglossal nerves. This

entails a full clearance of the submandibular triangle, involving the development of a subplatysmal skin flap (Figure 50.16a–e), dissection of periosteum along the lower border and inner aspect of the mandible, and delivery of the gland and tumour with a cuff of normal tissue. In cases of overt malignancy, modified neck dissection or radical neck dissection is appropriate. This may necessitate sacrifice of the lingual and hypoglossal nerves if the tumour is adherent to the deep bed of the gland (Figure 50.17a–d).

THE PAROTID GLAND

Anatomy

The parotid gland lies in a recess bounded by the ramus of the mandible, the base of the skull and the mastoid process. It lies on the carotid sheath and the XIth and XIIth cranial nerves and extends forward over the masseter muscle. The gland is enclosed in a sheath of dense deep cervical fascia. Its upper pole extends just below the zygoma and its lower pole into the neck.

Several important structures run through the parotid gland. These include:

- branches of the facial nerve;
- the terminal branch of the external carotid artery that divides into the maxillary artery and the superficial temporal artery;

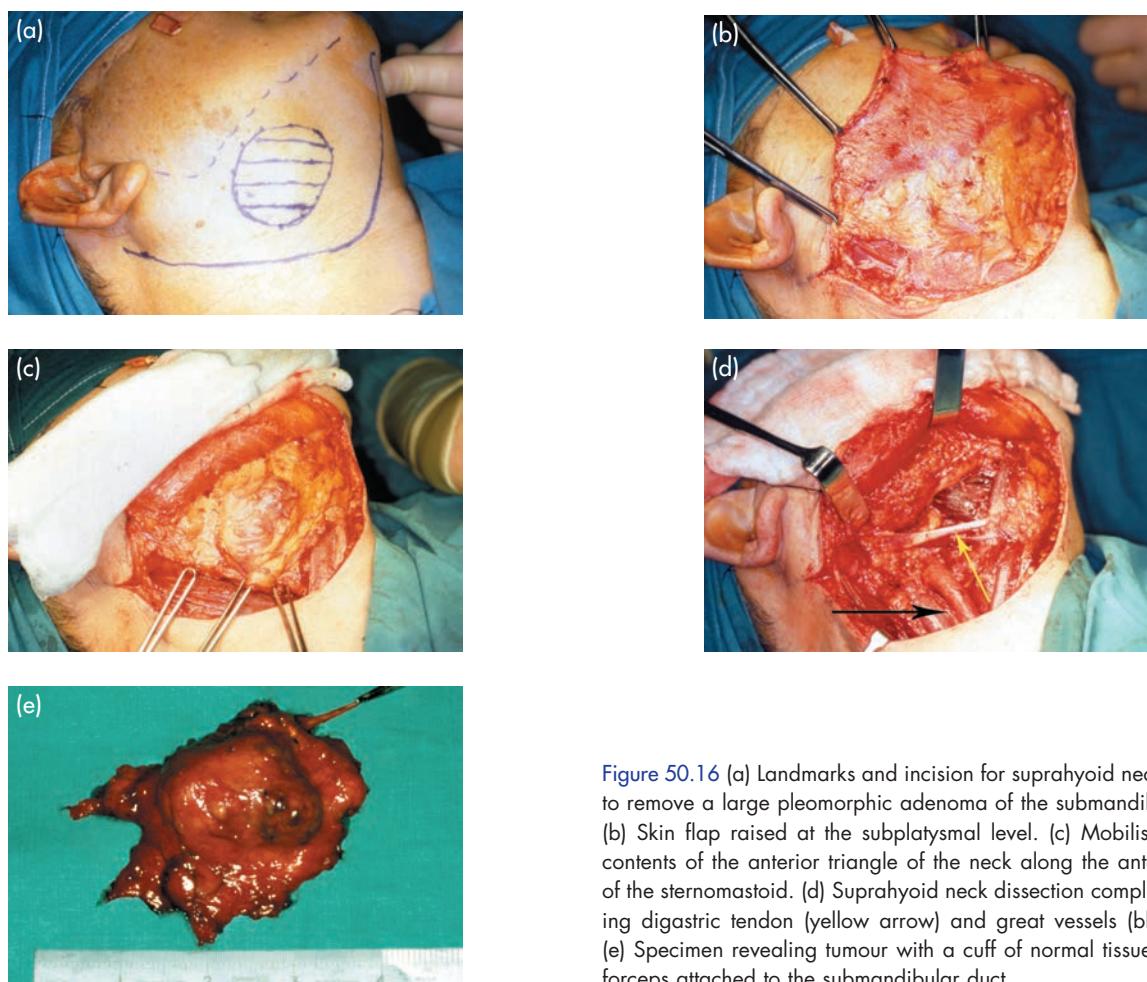

Figure 50.16 (a) Landmarks and incision for suprahyoid neck dissection to remove a large pleomorphic adenoma of the submandibular gland. (b) Skin flap raised at the subplatysmal level. (c) Mobilisation of the contents of the anterior triangle of the neck along the anterior border of the sternomastoid. (d) Suprahyoid neck dissection completed, revealing digastric tendon (yellow arrow) and great vessels (black arrow). (e) Specimen revealing tumour with a cuff of normal tissue with artery forceps attached to the submandibular duct.

- the retromandibular vein;
- intraparotid lymph nodes.

The gland is arbitrarily divided into deep and superficial lobes, separated by the facial nerve. Eighty per cent of the parotid gland lies superficial and 20 per cent deep to the nerve. An accessory lobe is occasionally present lying anterior to the superficial lobe on the masseter muscle.

Developmental disorders

Developmental disorders such as agenesis, duct atresia and congenital fistula are extremely rare.

Inflammatory disorders

Viral infections

Mumps is the most common cause of acute painful parotid swelling and predominantly affects children. It is spread via airborne droplets of infected saliva. The disease starts with a prodromal period of 1–2 days, during which the patient experiences fever, nausea and headache. This is followed by pain and swelling in one or both parotid glands. Parotid pain can be very severe and exacerbated by eating and drinking. Symptoms resolve within 5–10 days. The diagnosis is based on history and clinical examination; a recent contact with an infected patient with a painful parotid swelling is often sufficient to lead to a diagnosis. Atypical viral parotitis does occur and may present with predominantly unilateral swelling or even submandibular involvement. A single episode of infection confers lifelong

immunity. Treatment of mumps is symptomatic with regular paracetamol and adequate oral fluid intake. Complications of orchitis, oophoritis, pancreatitis, sensorineural deafness and meningoencephalitis are rare, but are more likely to occur in adults.

Other viral agents that produce parotitis include Coxsackie A and B, parainfluenza 1 and 3, Echo and lymphocytic choriomeningitis.

Bacterial infections

Acute ascending bacterial sialadenitis is historically described in dehydrated elderly patients following major surgery. Reduced salivary flow secondary to dehydration results in ascending infection via the parotid duct into the parotid parenchyma. Acute bacterial parotitis is now more common with no obvious precipitating factors. The patient presents with a tender, painful parotid swelling that arises over several hours (Figure 50.18). There is generalised malaise, pyrexia and occasional cervical lymphadenopathy. The pain is exacerbated by eating or drinking. The parotid swelling may be diffuse, but often localises to the lower pole of the gland. Intraoral examination may reveal pus exuding from the parotid gland papilla. The infecting organism is usually *Staphylococcus aureus* or *Streptococcus viridans*, and treatment is with appropriate intravenous antibiotics. If the gland becomes fluctuant, ultrasound may identify abscess formation within the gland that may require aspiration with a large-bore needle or formal drainage under general anaesthesia. In the latter procedure, the skin incision should be made low to avoid

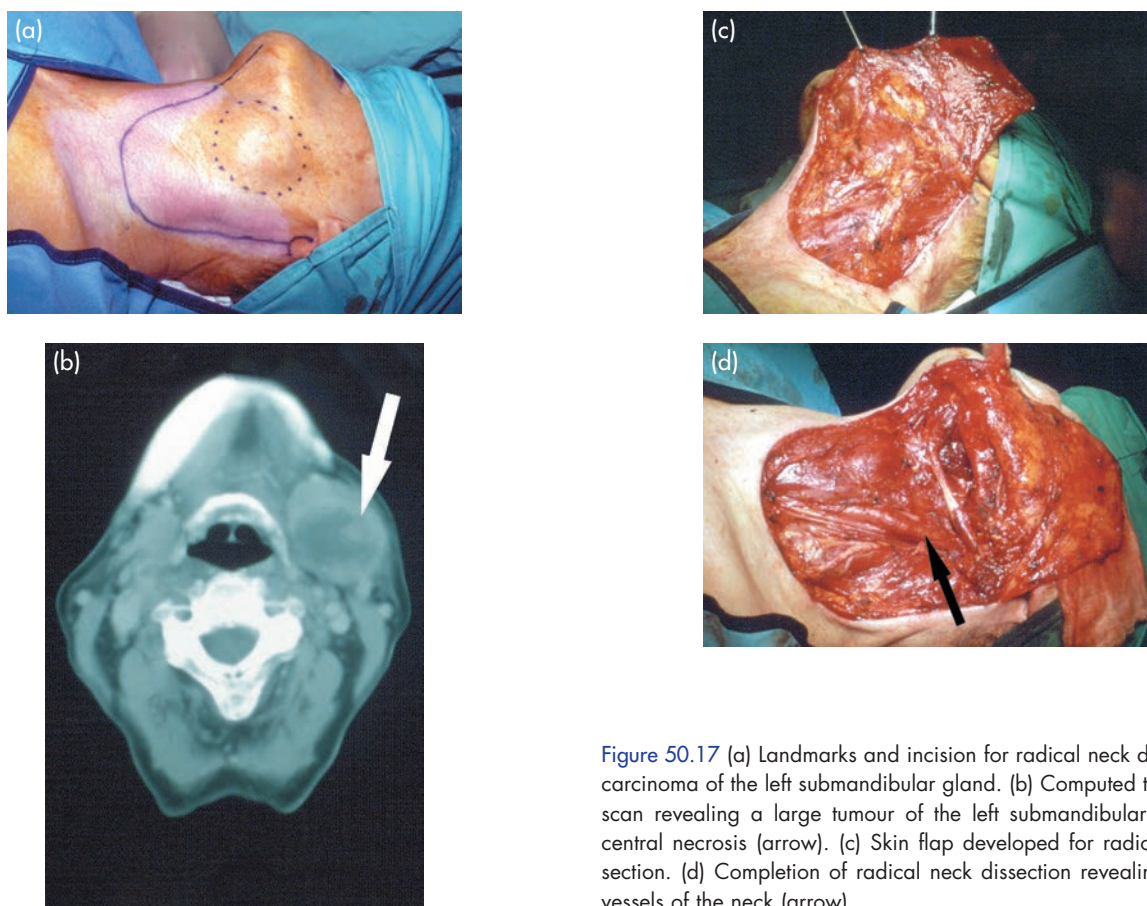

Figure 50.17 (a) Landmarks and incision for radical neck dissection for carcinoma of the left submandibular gland. (b) Computed tomographic scan revealing a large tumour of the left submandibular gland with central necrosis (arrow). (c) Skin flap developed for radical neck dissection. (d) Completion of radical neck dissection revealing the great vessels of the neck (arrow).

Figure 50.18 Acute left bacterial parotitis.

damage to the lower branch of the facial nerve. Blunt dissection using sinus forceps is preferred, and the cavity is opened to facilitate drainage. A drain is inserted and left *in situ* for 24–72 hours. Sialography is contraindicated during acute infection. Chronic bacterial sialadenitis is rare in the parotid gland.

Recurrent parotitis of childhood

Recurrent parotitis of childhood is a distinct clinical entity of unknown aetiology and variable prognosis. It is characterised by rapid swelling of one or both parotid glands, in which the symptoms are made worse by chewing and eating. Systemic upset with fever and malaise is variable. The symptoms usually last from 3 to 7 days, and are then followed by a quiescent period of weeks to several months. Children usually present between the ages of three and six years, although symptoms have been reported in infants as young as four months. The diagnosis is based on the characteristic history and can be confirmed by sialography. This shows a characteristic punctate sialectasis likened to a 'snowstorm' (Figure 50.19). The condition usually responds to short courses of antibiotics although, if recurrence is frequent, prophylactic low-dose antibiotics may be required for several months or even years. Few children require formal parotidectomy. However, if the onset of symptoms is late, e.g. adolescence/early adulthood, fewer patients respond to conservative measures and may require total conservative parotidectomy.

Figure 50.19 Characteristic 'snowstorm' appearance of recurrent parotitis of childhood (circled).

Human immunodeficiency virus-associated sialadenitis

Chronic parotitis in children is pathognomonic of human immunodeficiency virus (HIV) infection. The presentation of HIV-associated sialadenitis is very similar to classical Sjögren's syndrome in adulthood. Although HIV-associated sialadenitis and Sjögren's syndrome are histologically similar, the former condition is usually associated with a negative autoantibody screen. Other presentations of salivary gland disease in HIV-positive patients include multiple parotid cysts, which cause gross parotid swelling and facial disfigurement. CT and MRI demonstrate the characteristic 'Swiss cheese' appearance of multiple large cystic lesions (Figure 50.20). The swollen glands are usually painless and may regress on the institution of antiviral therapy. Parotidectomy, however, may be indicated to improve the appearance.

Obstructive parotitis

There are several causes of obstructive parotitis, which produces intermittent painful swelling of the parotid gland, particularly at mealtimes.

Papillary obstruction

Obstructive parotitis is less common than obstructive submandibular sialadenitis but, nevertheless, can be caused by trauma to the parotid papilla through either an overextended upper denture flange or a fractured upper molar tooth. The subsequent inflammation and oedema obstructs salivary flow, particularly at mealtimes. The patient usually experiences rapid onset pain and swelling at mealtimes. If left untreated, progressive scarring and fibrosis in and around the parotid duct papilla will produce a permanent stenosis. Symptoms are unlikely to resolve unless a papillotomy is performed. This is a simple procedure performed under either local or general anaesthesia. The parotid duct is

Figure 50.20 Magnetic resonance imaging scan. Giant bilateral parotid cysts in human immunodeficiency virus infection.

Figure 50.21 (a) Benign tumour of the left parotid gland producing characteristic deflection of the ear lobe. (b) Pleomorphic adenoma arising from the upper pole of the left parotid gland producing a pre-auricular swelling. (c) Deep lobe tumour of the right parotid presenting with a swelling of the right soft palate. (d) Magnetic resonance imaging scan revealing a large deep lobe tumour (arrow) of the right parotid gland, occupying the parapharyngeal space.

cannulated, and the distal parotid duct is laid open by incising longitudinally down onto the probe allowing free drainage of saliva.

Stone formation

Sialolithiasis is less common in the parotid gland (20 per cent) than in the submandibular gland (80 per cent). Parotid duct stones are usually radiolucent and rarely visible on plain radiography. They are frequently located at the confluence of the collecting ducts or located in the distal aspect of the parotid duct adjacent to the parotid papilla. Parotid gland sialography is usually required to identify the stone. A stone located in the collecting duct or within the gland may be managed by either endoscopic retrieval, lithotripsy or, least likely, surgical removal via a parotidectomy approach.

Tumours of the parotid gland

The parotid gland is the most common site for salivary tumours. Most tumours arise in the superficial lobe and present as slow-growing, painless swellings below the ear (Figure 50.21a), in front of the ear (Figure 50.21b) or in the upper aspect of the neck. Less commonly, tumours may arise from the accessory lobe and present as persistent swellings within the cheek. Rarely, tumours may arise from the deep lobe of the gland and present

as parapharyngeal masses (Figure 50.21c and d). Symptoms include difficulty in swallowing and snoring. Clinical examination reveals a diffuse firm swelling in the soft palate and tonsil.

Some 80–90 per cent of tumours of the parotid gland are benign, the most common being pleomorphic adenoma (Table 50.2).

Malignant salivary gland tumours are divided into two distinct subgroups:

- 1 **Low-grade malignant tumours**, e.g. acinic cell carcinoma, are indistinguishable on clinical examination from benign neoplasms.
- 2 **High-grade malignant tumours** usually present as rapidly growing, often painless swellings in and around the parotid gland. The tumour presents as either a discrete mass with infiltration into the overlying skin (Figure 50.22) or a diffuse but hard swelling of the gland with no discrete mass. Presentation with advanced disease is common, and cervical lymph node metastases may be present.

Investigations

CT and MRI scanning are the most useful imaging techniques (Figure 50.23a and b). Fine-needle aspiration biopsy may aid in obtaining a preoperative diagnosis, but open surgical biopsy

Table 50.2 Classification of salivary gland tumours (simplified).

Type	Subgroup	Common examples
I Adenoma	Pleomorphic Monomorphic	Pleomorphic adenoma Adenolymphoma (Warthin's tumour)
II Carcinoma	Low grade	Acinic cell carcinoma Adenoid cystic carcinoma Low-grade mucoepidermoid carcinoma
	High grade	Adenocarcinoma Squamous cell carcinoma High-grade mucoepidermoid carcinoma
III Non-epithelial tumours		Haemangioma, lymphangioma
IV Lymphomas	Primary lymphomas Secondary lymphomas	Non-Hodgkin's lymphomas Lymphomas in Sjögren's syndrome
V Secondary tumours	Local Distant	Tumours of the head and neck especially Skin and bronchus
VI Unclassified tumours		
VII Tumour-like lesions	Solid lesions	Benign lymphoepithelial lesion Adenomatoid hyperplasia
	Cystic lesions	Salivary gland cysts

is contraindicated unless malignancy is suspected, and preoperative histological diagnosis is required as a prelude to radical parotidectomy.

All tumours of the superficial lobe of the parotid gland should be managed by superficial parotidectomy. There is no role for enucleation even if a benign lesion is suspected. The aim of superficial parotidectomy is to remove the tumour with a cuff of normal surrounding tissue. The term 'suprafacial parotidectomy' has been used as not all branches of the facial nerve need be formally dissected, particularly if a tumour lies in the lower pole of the parotid gland.

Parotidectomy

Superficial parotidectomy

Superficial parotidectomy is the most common procedure for parotid gland pathology. Surgery is performed under endotracheal general anaesthesia, which may or may not be accompanied by hypotensive anaesthesia to facilitate dissection, improve the visual surgical field and reduce blood loss. The operation has several distinct phases.

Figure 50.22 Malignant tumour of the left parotid gland with invasion of the overlying skin.

Incision and development of a skin flap

The most commonly used incision is the 'lazy S' pre-auricular-mastoid-cervical (Figure 50.24a). The incision is marked out and marked at three points along its length to facilitate closure. Infiltration with local anaesthetic and adrenaline is optional, but does aid in the development of the skin flap, improves visibility and reduces blood loss in the initial phase. The skin flap is developed in an anterior direction by either scalpel or scissors dissection. The plane of dissection is well below the hair follicles, just above the parotid fascia. The skin flap is developed forwards to the anterior border of the gland. Posterior undermining of the incision in the cervical region facilitates access to the anterior border of the sternomastoid muscle.

Mobilisation of the gland

This phase of the dissection aims to free the posterior margin of the gland, allowing identification of the facial nerve. Clips are applied along the fascia overlying the sternomastoid muscle, with the assistant applying traction anteriorly. By sharp dissection along the anterior border of the sternomastoid, an avascular plane is developed (Figure 50.24b), which requires elective transection of the great auricular nerve. At the lower end of the dissection, the external jugular vein is often encountered and ligated. The gland is gradually mobilised by sharp dissection up to and on to the anterior aspect of the mastoid process, identifying the posterior belly of the digastric muscle.

A second avascular plane is developed along the anterior border of the cartilaginous and bony external auditory meatus immediately anterior to the tragus. The two avascular planes are then connected by blunt and sharp dissection. By developing two broad avascular planes, identification of the facial nerve trunk is facilitated (Figure 50.24c). It is best achieved by scissors dissection in the line of the facial nerve trunk. Use of a facial nerve stimulator is optional. Landmarks commonly used to aid identification of the trunk of the facial nerve are:

Figure 50.23 (a) Magnetic resonance imaging scan revealing a space-occupying lesion (arrow) in the right parotid gland; histology revealed pleomorphic adenoma. (b) Computed tomographic scan of the left parotid gland revealing a cystic lesion (arrow). Histology revealed acinic cell carcinoma.

- the inferior portion of the cartilaginous canal. This is termed Conley's pointer and indicates the position of the facial nerve, which lies 1 cm deep and inferior to its tip.
- the upper border of the posterior belly of the digastric muscle. Identification of this muscle not only mobilises the parotid gland, but also exposes an area immediately superior, in which the facial nerve is usually located.

Location of the facial nerve trunk

Once the facial nerve trunk is identified, gentle traction anteriorly facilitates further mobilisation. Control of haemorrhage at this stage is vital as bleeding, no matter how minor, significantly impedes visibility for the surgeon. Haemostasis can be achieved with bipolar diathermy, although caution is necessary, particularly when the facial nerve is approached. Damage to the stylo-mastoid artery, which lies immediately lateral to the nerve, can result in troublesome bleeding immediately prior to identification. Pledget swabs soaked in adrenaline are sometimes helpful in reducing the ooze associated with this phase of the dissection.

Dissection of the gland off the facial nerve

Once the facial nerve trunk is identified, further exposure of the branch of the facial nerve can be achieved by scissors dissection in the perineural plane immediately above the nerve. The tunnel thus created is then laid open, and divisions and branches of the facial nerve are followed to the periphery in a sequential manner, usually beginning with the upper division. The upper

division divides into a temporal and a zygomatic branch, and the lower division into mandibular and cervical branches. In this way, the superficial lobe and its associated tumour are mobilised in a superior to inferior direction (Figure 50.24d). The upper division of the nerve is frequently tortuous in its course and can be damaged unless great care is taken during perineural dissection. It is often not necessary to dissect all branches of the facial nerve completely, as adequate tumour clearance can be achieved with a more conservative resection of the superficial lobe. When a branch of the facial nerve is adherent to the tumour or running through the tumour, it may require elective division. With the exception of the buccal branch, the transected nerve should be repaired immediately with a cable graft, harvested from the great auricular nerve.

Closure

The patient is placed into a Trendelenburg position to identify any residual bleeding vessels. A suction drain is applied for a period of 24–48 hours, and the wound closed in layers (Figure 50.24f).

Radical parotidectomy

Radical parotidectomy is performed for patients in whom there is clear histological evidence of a high-grade malignant tumour, e.g. squamous cell carcinoma. Low-grade malignant tumours can usually be managed by standard superficial parotidectomy. Radical parotidectomy involves removal of all parotid gland tissue and elective sectioning of the facial nerve, usually through the main trunk (Figure 50.25a–f). The surgery inevitably removes the ipsilateral masseter muscle and may also require simultaneous neck dissection, particularly where there is clinical, radiological and cytological evidence of lymph node metastases in the ipsilateral neck.

Complications of parotid gland surgery

Complications of parotid gland surgery include:

- haematoma formation;
- infection;
- temporary facial nerve weakness;
- transection of the facial nerve and permanent facial weakness;
- sialocoele;
- facial numbness;
- permanent numbness of the ear lobe associated with great auricular nerve transection;
- Frey's syndrome.

Frey's syndrome

Frey's syndrome (gustatory sweating) is now considered an inevitable consequence of parotidectomy, unless preventative measures are taken (see below). It results from damage to the autonomic innervation of the salivary gland with inappropriate regeneration of parasympathetic nerve fibres that stimulate the sweat glands of the overlying skin. The clinical features include sweating and erythema over the region of surgical excision of the parotid gland as a consequence of autonomic stimulation of salivation by the smell or taste of food. The symptoms are entirely variable and are clinically demonstrated by a starch iodine test. This involves painting the affected area with iodine, which is allowed to dry before applying dry starch, which turns blue on exposure to iodine in the presence of sweat. Sweating

Figure 50.24 (a) Landmarks and cervical–mastoid pre-auricular incision for superficial parotidectomy. (b) Development of the avascular plane along the anterior border of the sternomastoid prior to sacrifice of the great auricular nerve. (c) Identification of the trunk of the facial nerve (arrow). (d) Diagram highlighting the anatomical landmarks of the parotid bed. (e) Branches of the facial nerve and retromandibular vein following delivery of the tumour. (f) Wound closure with a vacuum drain.

is stimulated by salivary stimulation. The management of Frey's syndrome involves the prevention as well as the management of established symptoms.

Prevention

There are a number of techniques described to prevent Frey's syndrome following parotidectomy. These include:

- sternomastoid muscle flap;
- temporalis fascial flap;
- insertion of artificial membranes between the skin and the parotid bed.

All these methods place a barrier between the skin and the parotid bed to minimise inappropriate regeneration of autonomic nerve fibres.

Management of established Frey's syndrome

Methods of managing Frey's syndrome include:

- antiperspirants, usually containing aluminium chloride;
- denervation by tympanic neurectomy;
- the injection of botulinum toxin into the affected skin.

The last is the most effective and can be performed as an out-patient.

Granulomatous sialadenitis

This is a group of rare conditions that affect the salivary glands producing a variety of signs and symptoms, particularly painless swellings of the parotid and/or submandibular glands. Systemic upset is variable. These include the following.

Mycobacterial infection

Tuberculosis and non-tuberculous sialadenitis typically present as a tumour-like swelling of the salivary gland. There is little pain and no fever. Preoperative investigations may be of some help, and the diagnosis is only confirmed when the swelling has

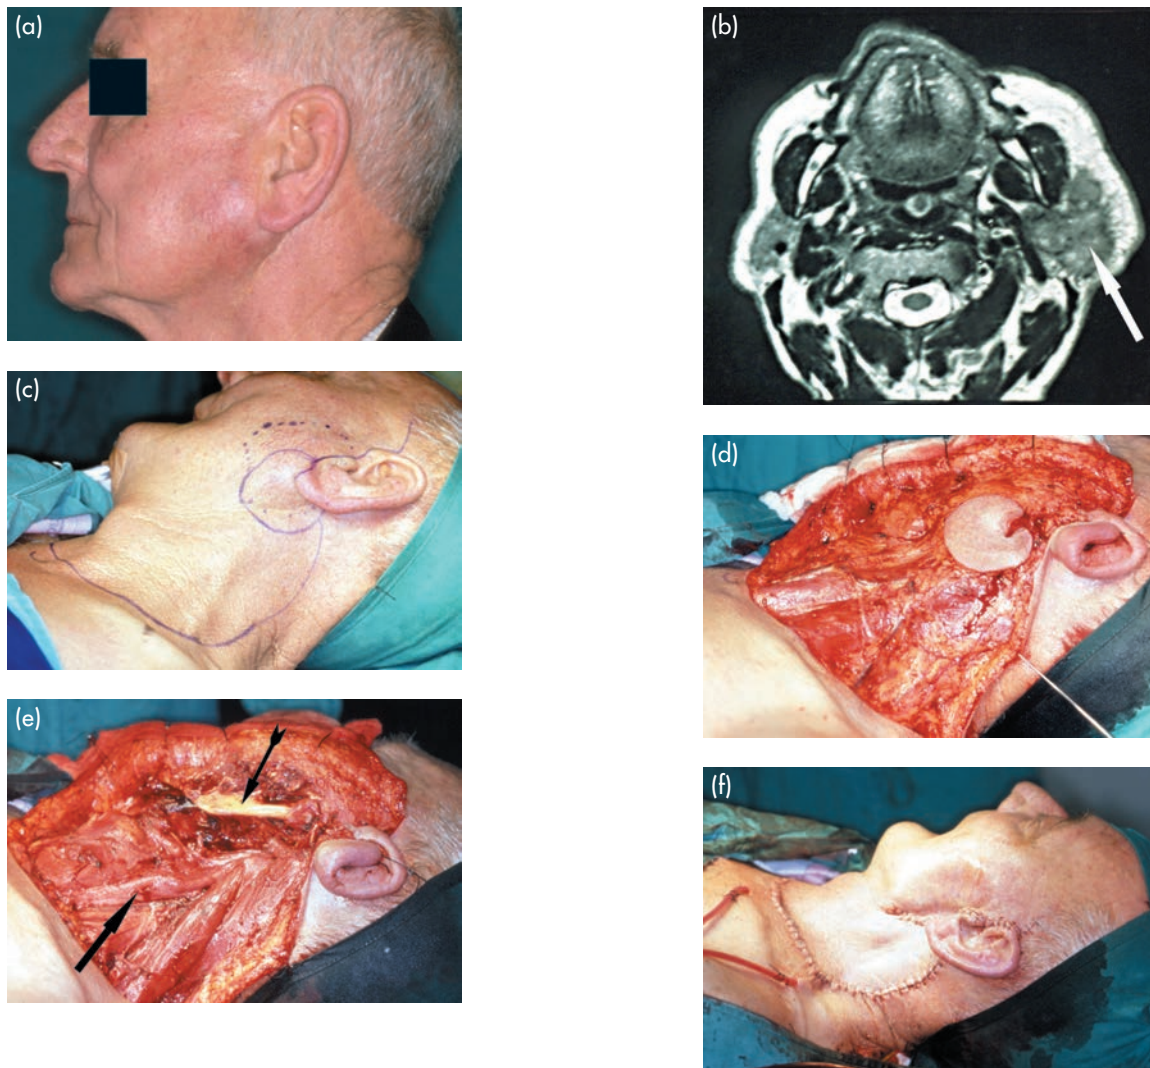

Figure 50.25 (a) High-grade malignant tumour in the left parotid gland. (b) Magnetic resonance imaging scan demonstrating a diffuse infiltrative malignant tumour of the left parotid gland (arrow). (c) Skin incision outlined for radical neck dissection and left radical parotidectomy including the removal of overlying skin. (d) Skin flap developed. (e) Appearance after left radical neck dissection and left radical parotidectomy. Posterior mandible (upper arrow) and great vessels of the neck (lower arrow) are visible. (f) Wound closure after left radical neck dissection.

been excised by either submandibular gland excision or formal parotidectomy.

Sarcoidosis

Sarcoidosis can affect the salivary tissue and presents with persistent salivary gland swelling that may be associated with xerostomia. Occasionally, the patient will present with a localised tumour-like swelling in one salivary gland, more commonly the parotid – the so-called sarcoid pseudotumour. In such circumstances, the diagnosis is only likely to be made following surgical excision for a presumed neoplasm.

Heerfordt's syndrome is sarcoidosis that involves parotid swelling, anterior uveitis, facial palsy and fever.

Other

These include cat scratch disease, toxoplasmosis, syphilis, deep mycoses and Wegener's granulomatosis, allergic sialadenitis and sialadenitis associated with radiotherapy of the head and neck.

Tumour-like lesions

There is a group of pathological conditions that affect the salivary glands which do not fall into any particular classification or category and are often difficult to diagnose. These include such conditions as sialadenosis, adenomatoid hyperplasia and multifocal monomorphic adenomatosis.

Sialadenosis

Sialadenosis (sialosis) is used to describe non-inflammatory swelling particularly affecting the parotid gland. It is usually occurs in association with a variety of conditions including diabetes mellitus, alcoholism, other endocrine diseases, pregnancy, drugs, bulimia and other eating disorders, and idiopathic diseases.

Most patients present between 40 and 70 years of age, and the salivary swellings are soft and often symmetrical (Figure 50.26). When the parotid glands are affected, patients may complain of

a hamster-like appearance. Drug-induced sialosis is particularly common with sympathomimetic drugs. In many patients, no underlying disorder can be identified. Severe and prolonged malnutrition, as seen in eating disorders, produces sialadenosis by a process of glandular atrophy and fatty replacement. The pathological mechanism of sialadenosis can be associated with a process of neuropathy, which interferes with salivary gland function and subsequent acinar cell atrophy. This may be the case in diabetes mellitus, where autonomic neuropathy is a recognised complication as well as drug-induced sialosis.

The treatment of sialosis is unsatisfactory, but treatment is aimed at the correction of the underlying disorder. Drug-associated sialadenosis may regress when the drug responsible is withdrawn.

Degenerative conditions

Sjögren's syndrome

Sjögren's syndrome is an autoimmune condition causing progressive destruction of salivary and lacrimal glands. Primary Sjögren's syndrome differs from secondary Sjögren's syndrome in that xerostomia and keratoconjunctivitis sicca occur without the associated connective tissue disorder. However, the symptoms are often more severe, and the incidence of lymphomatous transformation (see below) in the primary group is higher than that in the secondary group (Table 50.3).

Table 50.3 Degenerative disorders.

Primary Sjögren's syndrome	More severe xerostomia Widespread exocrine gland dysfunction No connective tissue disorder
Secondary Sjögren's syndrome	M:F: 1:10 Middle age Underlying connective tissue disorder
Benign lymphoepithelial lesion	20% develop lymphoma Diffuse parotid swelling 20% bilateral

Females are affected more than males in the ratio 10:1. Occasionally, there is enlargement of the salivary glands, more commonly the parotid rather than the submandibular glands. The glands are occasionally painful, and the patient sometimes develops a bacterial sialadenitis due to ascending infection from the associated xerostomia.

The characteristic pathological feature of Sjögren's syndrome is the progressive lymphocytic infiltration, acinar cell destruction and proliferation of duct epithelium in all salivary and lacrimal gland tissue. The diagnosis is based on the history as no single laboratory investigation is pathognomonic of either primary or secondary Sjögren's syndrome (Figure 50.27).

Management

Management of Sjögren's syndrome remains symptomatic. No known treatment modifies or improves the xerostomia or keratoconjunctivitis sicca. An ophthalmological assessment is important, and artificial tears are essential to preserve corneal

Figure 50.26 Sialosis of the parotid glands secondary to excess alcohol intake.

function. For dry mouth, various artificial salivary substitutes are available, but patients often consume large volumes of water, carrying a bottle of water with them at all times. In the dentate patient, the use of salivary substitutes with fluoride is important to counter the risk of accelerating dental caries. Other oral complications include oral candidosis and accelerated periodontal disease.

Complications of Sjögren's syndrome

There is an increased incidence of developing lymphoma (most commonly monocytoid B-cell lymphoma) in patients with Sjögren's syndrome. The risk is highest within the primary group, and the onset of lymphoma is heralded by immunological change within the blood.

Figure 50.27 Clinical appearance of primary biliary cirrhosis associated with Sjögren's syndrome.

A hamster is a small nocturnal Eurasian rodent.

Benign lymphoepithelial lesion

The use of the word 'benign' to describe this lesion is misleading because 20 per cent of patients with benign lymphoepithelial lesion ultimately develop lymphoma. It is not possible to distinguish on histological grounds benign lymphoepithelial lesion from Sjögren's syndrome. Both are characterised by lymphocytic infiltration, acinar atrophy and ductal epithelial proliferation. Clinically, benign lymphoepithelial lesion presents as a diffuse swelling of the parotid gland. The swelling is firm, often painful and, in 20 per cent of patients, the presentation is bilateral. Most patients are female and over 50 years of age. Parotidectomy is often undertaken to establish a diagnosis. Prolonged follow up is essential.

Xerostomia

Xerostomia is a common symptom in many aspects of medical practice. Normal salivary flows decrease with age in both men and women, although many patients with xerostomia are postmenopausal women who also complain of a burning tongue or mouth. Common causes of xerostomia are:

- chronic anxiety states and depression;
- dehydration;
- anticholinergic drugs, especially antidepressants;
- salivary gland disorders – Sjögren's syndrome. Ascending parotitis is an occasional complication of xerostomia and is managed with antibiotics and increased fluid intake;
- radiotherapy to the head and neck.

Sialorrhoea

Certain drugs and oral infection produce a transient increase in salivary flow rates. In healthy individuals, excess salivation is rarely a symptom as excess saliva is swallowed spontaneously. Uncontrolled drooling is usually seen in the presence of normal salivary production. It is seen in children with mental and physical handicap, notably cerebral palsy.

Management

Uncontrollable drooling is managed surgically, and many operations are available. Surgical options include:

- bilateral submandibular duct repositioning and simultaneous sublingual gland excision;
- bilateral submandibular gland excision;
- transposition of the parotid ducts and simultaneous submandibular gland excision.

Most resting salivary gland flow arises from the submandibular glands, and surgery should be focused on this gland to control uncontrolled sialorrhoea.

CHAPTER 51

The thyroid and parathyroid glands

LEARNING OBJECTIVES

- To understand the development and anatomy of the thyroid and parathyroid glands
- To know the physiology and investigation of thyroid and parathyroid function
- To be able to select appropriate investigations for thyroid swellings
- To know how to treat thyrotoxicosis and thyroid failure
- To know when to operate on a thyroid swelling
- To describe thyroid lobectomy
- To describe the investigation and management of hyperparathyroidism
- To know the risks and complications of thyroid and parathyroid surgery

EMBRYOLOGY

The thyroglossal duct develops from the median bud of the pharynx. The foramen caecum at the base of the tongue is the vestigial remnant of the duct. This initially hollow structure migrates caudally and passes in close continuity with, and sometimes through, the developing hyoid cartilage. The parathyroid glands develop from the third and fourth pharyngeal pouches (Figure 51.1). The thymus also develops from the third pouch. As it descends it takes the associated parathyroid gland with it which explains why the inferior parathyroid which arises from the third pharyngeal pouch normally lies inferior to the superior gland. However, the inferior parathyroid may be found anywhere along this line of descent. The developing thyroid lobes amalgamate with the structures that arise in the fourth pharyngeal pouch, i.e. the superior parathyroid gland and the ultimobranchial body. Parafollicular cells (C cells) from the neural crest reach the thyroid via the ultimobranchial body.

SURGICAL ANATOMY

The normal thyroid gland weighs 20–25 g. The functioning unit is the lobule supplied by a single arteriole and consists of 24–40 follicles lined with cuboidal epithelium. The follicle contains colloid in which thyroglobulin is stored (Figure 51.2). The arterial supply is rich, and extensive anastomoses occur between the main thyroid arteries and branches of the tracheal and oesophageal arteries (Figure 51.3). There is an extensive lymphatic

network within the gland. Although some lymph channels pass directly to the deep cervical nodes, the subcapsular plexus drains principally to the central compartment juxtathyroid – ‘Delphian’ – and paratracheal nodes and nodes on the superior and inferior

Figure 51.1 Embryology of thyroid and parathyroid. Diagram of an anterior view of the pharynx in a 4-week embryo showing the relationship of the third and fourth pharyngeal pouches to final position of the thyroid and parathyroid glands. IPG, inferior parathyroid; SPG, superior parathyroid; UBB, ultimobranchial body.

Delphi, a sacred site near the Gulf of Corinth in Greece, is the place where Phythia, the snake-woman oracle, resided. She sat on a tripod clutching the ribbons of the monolithic ‘omphalos’ of the world and after inhaling sulphurous fumes, would utter meaningless jargon which was interpreted equivocally by the attendant priests for those who came to consult her. Formerly the purpose of these lymph nodes was uncertain, and they were therefore called ‘Delphic’.

Figure 51.2 Histology of the normal thyroid.

Figure 51.3 The thyroid gland from the front.

thyroid veins (level VI), and from there to the deep cervical (levels II, III, IV and V) and mediastinal groups of nodes (level VII) (Figure 51.4).

The normal parathyroid gland weighs up to 50 mg with a characteristic orange/brown colour and mobility within the surrounding fat and thymic tissue. Most adults have four parathyroid glands but supernumerary glands occur and nests of parathyroid tissue are commonly found in the thymus. The superior parathyroid is more consistent in position than the inferior. The superior gland is commonly found in fat above the inferior thyroid artery and close to the cricothyroid articulation. It should be noted that the anatomical and radiological site, usually described as above the artery and posterior to the recurrent laryngeal nerve (RLN), is different from the surgical anatomy when the thyroid lobe is mobilised and rotated anteriorly. When the superior gland enlarges it tends to pass behind the inferior thyroid artery and descend inferiorly behind the oesophagus. The inferior

Figure 51.4 Cervical lymph node levels.

parathyroid gland is usually found under the capsule of the upper horn of the thymus or on the inferior pole of the thyroid lobe. A maldescended gland, however, can be found anywhere along the line of descent, virtually from the base of the skull to the aortopulmonary window (Figure 51.5) (Summary box 51.1).

Summary box 51.1

Embryology and anatomy

- Know the embryology of the thyroid and parathyroid glands
- Know the surgical and radiological anatomy of the thyroid

Figure 51.5 Surgical anatomy of the thyroid. The situation after mobilisation of the right lobe, and the relationships of the recurrent laryngeal nerve, inferior thyroid artery and the parathyroid glands as they are usually found. 1 and 2, common sites for superior parathyroid gland – the arrow shows the tendency for an enlarged gland to migrate from position 1 to position 2, i.e. in an inferior direction, to lie posterior to the inferior thyroid artery (5) and oesophagus (8); 3 and 4, common sites for inferior parathyroid gland (the upper horn of the thymus points like an index finger to the inferior parathyroid, which may lie under the fingernail); 5, recurrent laryngeal nerve; 6, thymus; 7, oesophagus. (see Figure 51.52).

PHYSIOLOGY

Thyroxine

The hormones tri-iodothyronine (T_3) and L-thyroxine (T_4) (extracted by EC Kendall in 1915) are bound to thyroglobulin within the colloid. Synthesis within the thyroglobulin complex is controlled by several enzymes, in distinct steps:

- trapping of inorganic iodide from the blood;
- oxidation of iodide to iodine;
- binding of iodine with tyrosine to form iodotyrosines;
- coupling of monoiodotyrosines and di-iodotyrosines to form T_3 and T_4 .

When hormones are required, the complex is resorbed into the cell and thyroglobulin is broken down. T_3 and T_4 are liberated and enter the blood, where they are bound to serum proteins: albumin, thyroxine-binding globulin (TBG) and thyroxine-binding prealbumin (TBPA). The small amount of hormone that remains free in the serum is biologically active.

The metabolic effects of the thyroid hormones are due to unbound free T_4 and T_3 (0.03 and 0.3 per cent of the total circulating hormones, respectively). T_3 is the more important physiological hormone and is also produced in the periphery by conversion from T_4 . T_3 is quick acting (within a few hours), whereas T_4 acts more slowly (4–14 days).

Parathormone

The parathyroid glands secrete the 84-amino acid peptide parathyroid hormone (PTH), which controls the level of serum calcium in extracellular fluid. PTH is released in response to a low serum calcium or high serum magnesium level. PTH activates osteoclasts to resorb bone, and increases calcium reabsorption from urine and renal activation of vitamin D with subsequent increased gut absorption of calcium. Renal excretion of phosphate is also increased.

Calcitonin

The parafollicular C cells of the thyroid are of neuroendocrine origin and arrive in the thyroid via the ultimobranchial body (Figure 51.1). They produce calcitonin which is a serum marker for recurrence of medullary thyroid cancer.

The pituitary–thyroid axis

Synthesis and liberation of thyroid hormones from the thyroid

Edward Calvin Kendall, 1886–1972, Professor of Physiological Chemistry, the Graduate Medical School, The Mayo Foundation, Rochester, MN, USA. He shared the 1950 Nobel Prize for Physiology or Medicine with Hench and Reichstein 'for their discoveries concerning the suprarenal hormones, their structure and biological effects'.

is controlled by thyroid-stimulating hormone (TSH) from the anterior pituitary. Secretion of TSH depends upon the level of circulating thyroid hormones and is modified in a classic negative feedback manner. In hyperthyroidism, when hormone levels in the blood are high, TSH production is suppressed whereas in hypothyroidism it is stimulated. Regulation of TSH secretion also results from the action of thyrotrophin-releasing hormone (TRH) produced in the hypothalamus.

Thyroid-stimulating antibodies

A family of IgG immunoglobulins bind with TSH receptor sites (TRAbs) and activate TSH receptors on the follicular cell membrane. They have a more protracted action than TSH (16–24 versus 1.5–3 hours) and are responsible for virtually all cases of thyrotoxicosis not due to autonomous toxic nodules. Serum concentrations are very low but their measurement is not essential to make the diagnosis.

Therapeutic notes

T_4 is given once daily; an average replacement dose is 0.15 mg and a suppressive dose is 0.2 mg. T_3 is given three times daily, usually as a suppressive dose of 20 µg three times a day. Recombinant human TSH is now available and is used to maximise (radioactive) iodine uptake as an alternative to thyroid hormone withdrawal.

TESTS OF THYROID FUNCTION

There is a large variety of tests of thyroid function available to the endocrinologist; however, in a surgical setting investigations requested should be the minimum necessary to reach a diagnosis and formulate a management plan. Only a small number of parameters need to be measured as a routine, although this may require supplementation or to be repeated when inconclusive.

Serum thyroid hormones

Serum TSH

TSH levels can be measured accurately down to very low serum concentrations with an immunochemiluminometric assay. When the serum TSH level is in the normal range, it is redundant to measure the T_3 and T_4 levels. Interpretation of deranged TSH levels, however, depends on knowledge of the T_3 and T_4 values (Table 51.1). In the euthyroid state, T_3 , T_4 and TSH levels will all be within the normal range. Florid thyroid failure results in depressed T_3 and T_4 levels, with gross elevation of the TSH. Incipient or developing thyroid failure is characterised by low normal values of the T_3 and T_4 and elevation of the TSH. In toxic states, the TSH level is suppressed and undetectable.

Table 51.1 Results of thyroid function tests in normal and pathological states.

Thyroid functional state	TSH (0.3–3.3 mU/L)	Free T_4 (10–30 nmol/L)	Free T_3 (3.5–7.5 µmol/L)
Euthyroid	Normal	Normal	Normal
Thyrotoxic	Undetectable	High	High
Myxoedema	High	Low	Low
Suppressive T_4 therapy	Undetectable	High	High (often normal)
T_3 toxicity	Low/undetectable	Normal	High

Thyroxine (T_4) and tri-iodothyronine (T_3)

These are transported in plasma bound to specific proteins (TBG). Only a small fraction of the total (0.03 per cent of T_4 and 0.3 per cent of T_3) is free and physiologically active. Assays of total hormone for both are now obsolete because of the confounding effect of circulating protein concentrations, influenced by the level of circulating oestrogen and nutritional state. Highly accurate radioimmunoassays of free T_3 and free T_4 are now routine. T_3 toxicity (with a normal T_4) is a distinct entity and may only be diagnosed by measuring the serum T_3 , although a suppressed TSH level with a normal T_4 may suggest the diagnosis.

An appropriate combination to establish the functional thyroid status at initial assessment is serum TSH and assay of antithyroid antibodies supplemented by free T_4 and T_3 evaluation when TSH is abnormal.

Thyroid autoantibodies

Serum levels of antibodies against thyroid peroxidase (TPO) (previously referred to as thyroid microsomal antigen) and thyroglobulin are useful in determining the cause of thyroid dysfunction and swellings. Autoimmune thyroiditis may be associated with thyroid toxicity, failure or euthyroid goitre. Levels above 25 units/mL for TPO antibody and titres of greater than 1:100 for antithyroglobulin are considered significant, although a proportion of patients with histological evidence of lymphocytic (autoimmune) thyroiditis are seronegative. The presence of antithyroglobulin antibody interferes with assays of serum thyroglobulin with implications for follow up of thyroid cancers. TSH receptor antibodies (TSH-Rab or TRAB) are often present in Graves' disease. They are largely produced within the thyroid itself (Summary box 51.2).

Summary box 51.2

Thyroid investigations

Essential

- Serum: TSH (T_3 and T_4 if abnormal); thyroid autoantibodies
- FNAC of palpable discrete swellings; ultrasound guidance may reduce the 'Thy1' rate

Optional

- Corrected serum calcium
- Serum calcitonin (carcinoembryonic antigen may be used as an alternative screening test for medullary cancer)
- Imaging: chest radiograph and thoracic inlet if tracheal deviation/retrosternal goitre; ultrasound, CT and MRI scan for known cancer, some reoperations and some retrosternal goitres; isotope scan if discrete swelling and toxicity coexist

Thyroid imaging

Chest and thoracic inlet x-rays

Simple radiographs of the chest and thoracic inlet will rapidly and economically confirm the presence of significant retrosternal goitre and clinically important degrees of tracheal deviation and compression (Figure 51.6). Chest x-ray tends to underestimate the extent of retrosternal extensions. Pulmonary metastases may also be detected.

Ultrasound scanning

Ultrasound scanning gives good anatomical images of the

Figure 51.6 Chest radiograph showing retrosternal goitre with tracheal displacement.

thyroid and surrounding structures and while previously out of favour, high frequency ultrasound is now widely used (Figure 51.7). The drawback of ultrasound is that it may reveal thyroid swellings that are not clinically relevant and risks a cascade of unnecessary investigation, intervention and anxiety when used indiscriminately. However, in experienced hands, ultrasound can reduce the number of unsatisfactory aspiration cytology samples by permitting more targeted sampling, and is very reliable in the identification of nodes involved in thyroid cancer and the identification of larger parathyroid adenomas.

Figure 51.7 Ultrasound scanning. (a) Transverse scan of normal thyroid. R, right lobe; L, left lobe; T, trachea. (b) Longitudinal scan of normal jugular lymph nodes (white arrows).

Computed tomography, magnetic resonance imaging and positron emission tomography scanning

Routine computed tomography (CT) and magnetic resonance imaging (MRI) of unexceptional thyroid swellings is not indicated and is reserved for the assessment of known malignancy, to assess the extent of retrosternal and occasionally recurrent goitres (Figure 51.8). Iodine containing contrast agents may interfere with subsequent radioactive iodine uptake used for diagnostic scanning or therapy. The appearance and reporting of a retrosternal goitre on CT can give a misleading impression of the operative difficulty in delivery through a neck incision.

Positron emission tomography (PET)/CT scanning has an occasional role in the management of patients with obscure recurrent thyroid cancer but increasingly identifies incidental thyroid cancers in patients undergoing this investigation for other malignancies.

Isotope scanning

The uptake by the thyroid of a low dose of either radiolabelled iodine (^{123}I) or the cheaper technetium ($^{99\text{m}}\text{Tc}$) will demonstrate the distribution of activity in the whole gland (Figure 51.9). Routine isotope scanning is unnecessary and inappropriate for distinguishing benign from malignant lesions because the majority (80 per cent) of 'cold' swellings are benign and some (5 per cent) functioning or 'warm' swellings will be malignant. Its principal value is in the toxic patient with a nodule or nodularity of the thyroid. Localisation of overactivity in the gland

will differentiate between a toxic nodule with suppression of the remainder of the gland, and toxic multinodular goitre with several areas of increased uptake with important implications for therapy.

Whole body scanning is used to demonstrate metastases, but the patient must have all normally functioning thyroid tissue ablated either by surgery or radioiodine before the scan is performed, because metastatic thyroid cancer tissue cannot compete with normal thyroid tissue in the uptake of iodine.

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the outpatient department and is readily repeated. This technique, developed in Scandinavia 40 years ago, is now routine throughout the world. FNAC results should be reported using standard terminology (Table 51.2). There is a trend to use ultrasound to guide the needle to achieve more accurate sampling and reduce the rate of unsatisfactory aspirates.

HYPOTHYROIDISM

A scheme for classifying hypothyroidism is given in Table 51.3.

Cretinism (fetal or infantile hypothyroidism)

Cretinism is the consequence of inadequate thyroid hormone production during fetal and neonatal development. 'Endemic

Table 51.3 Classification of hypothyroidism.

Autoimmune thyroiditis (chronic lymphocytic thyroiditis)	Non-goitrous: primary myxoedema Goitrous: Hashimoto’s disease
Iatrogenic	After thyroidectomy After radioiodine therapy Drug induced (antithyroid drugs, para-aminosalicylic acid and iodides in excess)
Dyshormonogenesis	
Goitrogens	
Secondary to pituitary or hypothalamic disease	
Thyroid agenesis	
Endemic cretinism	Often goitrous and due to iodine deficiency

cretinism’ is due to dietary iodine deficiency, whereas sporadic cases are due either to an inborn error of thyroid metabolism or complete or partial agenesis of the gland. A hoarse cry, macroglossia and umbilical hernia in a neonate with features of thyroid failure suggest the diagnosis. Immediate diagnosis and treatment with thyroxine within a few days of birth are essential to prevent *in utero* damage progressing and if physical and mental development is to be normal. In non-endemic areas and societies with iodised salt, sporadic hypothyroidism still occurs in 1 in 4000 live births, and biochemical screening of neonates for hypothyroidism using TSH and T₄ assays on a heel-prick blood sample is widespread. Women taking antithyroid drugs may give birth to a hypothyroid infant and radioactive iodine must never be given to pregnant women.

Adult hypothyroidism

The term myxoedema should be reserved for severe thyroid failure and not applied to the much more common mild thyroid deficiency. The signs of thyroid deficiency are:

- bradycardia
- cold extremities
- dry skin and hair
- periorbital puffiness
- hoarse voice
- bradykinesia, slow movements
- delayed relaxation phase of ankle jerks.

The symptoms are:

- tiredness
- mental lethargy
- cold intolerance
- weight gain
- constipation
- menstrual disturbance
- carpal tunnel syndrome.

Comparison of the facial appearance with a previous photograph may be helpful. Delayed relaxation of the ankle jerk reflex is the most useful clinical sign in making the diagnosis.

Thyroid function tests

These show low T₄ and T₃ levels with a high TSH (except in the rare event of pituitary failure) (Table 51.1). High serum levels of TPO antibodies are characteristic of autoimmune disease.

Treatment

Oral thyroxine (0.10–0.20 mg) as a single daily dose is curative. Caution is required in the elderly or those with cardiac disease and the replacement dose is then commenced at 0.05 mg daily and increased cautiously. If a rapid response is required, triiodothyronine (20 µg three times a day) may be used.

Myxoedema

The signs and symptoms of hypothyroidism are accentuated. The facial appearance is typical, and there is often supraclavicular puffiness, a malar flush and a yellow tinge to the skin (Figure 51.10). Myxoedema coma, characterised by altered mental state, hypothermia and a precipitating medical condition, for example cardiac failure or infection, carries a high mortality. Treatment comprises thyroid replacement, either a bolus of 0.50 mg of T₄ or 10 µg of T₃ either i.v. or orally every 4–6 hours. If the body

in utero is Latin for ‘in the uterus’.
Myxoedema was first described in 1873 by Sir William Withey Gull, 1816–1890, physician, Guy’s Hospital, London, UK.

Figure 51.10 Myxoedema. Note the bloated look, pouting lips and dull expression (courtesy of Dr VK Summers, Liverpool, UK).

temperature is less than 30°C, the patient must be warmed slowly. Intravenous broad-spectrum antibiotics and hydrocortisone (in divided doses) are recommended.

Primary or atrophic myxoedema is considered to be an autoimmune disease similar to chronic lymphocytic (Hashimoto's) thyroiditis (see below) but without goitre formation. Delay in diagnosis is common and the degree of hypothyroidism is usually more severe than in goitrous autoimmune thyroiditis.

Dyshormonogenesis

Genetic deficiencies in the enzymes controlling the synthesis of thyroid hormones account for a minority of cases of neonatal hypothyroidism and goitre. These are usually inherited in an autosomal recessive pattern and a family history is common. If the biochemical effect is of moderate degree, thyroid enlargement may be the only manifestation and dyshormonogenesis should be considered in young patients presenting with euthyroid goitre. The most common abnormalities affect TPO activity and thyroglobulin synthesis. A classic example of dyshormonogenesis due to TPO deficiency is Pendred syndrome, in which goitre is associated with severe sensorineural hearing impairment and abnormality of the bony labyrinth observed on CT examination of the temporal bones.

THYROID ENLARGEMENT

The normal thyroid gland is impalpable. The term goitre (from the Latin guttur = the throat) is used to describe generalised enlargement of the thyroid gland. A discrete swelling (nodule) in one lobe with no palpable abnormality elsewhere is termed an isolated (or solitary) swelling. Discrete swellings with evidence of abnormality elsewhere in the gland are termed dominant (Summary box 51.3).

Hakaru Hashimoto, 1881–1934, Director of The Hashimoto Hospital, Mie, Japan, described chronic lymphocytic thyroiditis in 1912. The link to an autoimmune basis was defined by Roitt and his co-workers.

Ivan Maurice Roitt, born 1927, Emeritus Professor of Immunology, University College, London, UK. Elected Fellow of The Royal Society of London in 1983.
Vaughan Pendred, 1869–1946, a general practitioner of Durham, UK, described this syndrome in 1896. Exactly 100 years later the defect was mapped to chromosome 7q.

Summary box 51.3

Thyroid swellings

- Know how to describe thyroid swellings
- Use appropriate investigations
- Know the indications for surgery
- Select the appropriate procedure
- Describe and manage postoperative complications

A scheme for classifying thyroid enlargement is given in Table 51.4.

Table 51.4 Classification of thyroid swellings.

Simple goitre (euthyroid)	Diffuse hyperplastic	Physiological Pubertal Pregnancy
	Multinodular goitre	
Toxic	Diffuse (Graves' disease)	
	Multinodular	
	Toxic adenoma	
Neoplastic	Benign	
	Malignant	
Inflammatory	Autoimmune	Chronic lymphocytic thyroiditis Hashimoto's disease
	Granulomatous	De Quervain's thyroiditis
	Fibrosing	Riedel's thyroiditis
	Infective	Acute (bacterial thyroiditis, viral thyroiditis, 'subacute thyroiditis')
		Chronic (tuberculous, syphilitic)
	Other	Amyloid

Simple goitre

Aetiology

Simple goitre may develop as a result of stimulation of the thyroid gland by TSH, either as a result of inappropriate secretion from a microadenoma in the anterior pituitary (which is rare), or in response to a chronically low level of circulating thyroid hormones. The most important factor in endemic goitre is dietary deficiency of iodine (see below) but defective hormone synthesis probably accounts for many sporadic goitres (see below).

TSH is not the only stimulus to thyroid follicular cell proliferation and other growth factors, including immunoglobulins, exert an influence. The heterogeneous structural and functional response in the thyroid resulting in characteristic nodularity may

Figure 51.11 Total thyroidectomy for dys hormonogenetic goitre in a 14-year-old girl.

be due to the presence of clones of cells particularly sensitive to growth stimulation.

Iodine deficiency

The daily requirement of iodine is about 0.1–0.15 mg. In nearly all districts where simple goitre is endemic, there is a very low iodide content in the water and food. Endemic areas are in mountain ranges, such as the Rockies, Alps, Andes and Himalayas, and in the UK, areas of Derbyshire and Yorkshire. Endemic goitre is also found in lowland areas where the soil lacks iodide or the water supply comes from distant mountain ranges, e.g. the Great Lakes of North America, the plains of Lombardy, the Struma valley, the Nile valley and the Congo. Calcium is also goitrogenic and goitre is common in low iodine areas on chalk or limestone, for example Derbyshire and southern Ireland. Although iodides in food and water may be adequate, failure of intestinal absorption may produce iodine deficiency.

Dys hormonogenesis

Enzyme deficiencies of varying severity may be responsible for many sporadic goitres, i.e. in non-endemic areas (Figure 51.11). There is often a family history, suggesting a genetic defect. Environmental factors may compensate in areas of high iodine intake, e.g. goitre is almost unknown in Iceland where the fish diet is rich in iodine. Similarly, a low intake of iodine encourages goitre formation in those with a metabolic predisposition.

Goitrogens

Well-known goitrogens are the vegetables of the brassica family (cabbage, kale and rape), which contain thiocyanate, drugs such as para-aminosalicylic acid (PAS) and, of course, the antithyroid drugs. Thiocyanates and perchlorates interfere with iodide trapping; carbimazole and thiouracil compounds interfere with the oxidation of iodide and the binding of iodine to tyrosine.

Struma. The River Struma arises in the mountains of Bulgaria and flows into the Aegean Sea. Along its banks and those of its tributaries dwell peoples of several nationalities among whom endemic goitre has long been prevalent. Struma is a European continental term for goitre.

Surprisingly enough, iodides in large quantities are goitrogenic because they inhibit the organic binding of iodine and produce an iodide goitre. Excessive iodine intake may be associated with an increased incidence of autoimmune thyroid disease.

The natural history of simple goitre

Stages in goitre formation are:

- Persistent growth stimulation causes diffuse hyperplasia; all lobules are composed of active follicles and iodine uptake is uniform. This is a diffuse hyperplastic goitre, which may persist for a long time but is reversible if stimulation ceases.
- Later, as a result of fluctuating stimulation, a mixed pattern develops with areas of active lobules and areas of inactive lobules.
- Active lobules become more vascular and hyperplastic until haemorrhage occurs, causing central necrosis and leaving only a surrounding rind of active follicles.
- Necrotic lobules coalesce to form nodules filled either with iodine-free colloid or a mass of new but inactive follicles.
- Continual repetition of this process results in a nodular goitre. Most nodules are inactive, and active follicles are present only in the internodular tissue.

Diffuse hyperplastic goitre

Diffuse hyperplasia corresponds to the first stages of the natural history. The goitre appears in childhood in endemic areas but, in sporadic cases, it usually occurs at puberty when metabolic demands are high. If TSH stimulation ceases, the goitre may regress, but tends to recur later at times of stress, such as pregnancy. The goitre is soft, diffuse and may become large enough to cause discomfort. A colloid goitre is a late stage of diffuse hyperplasia when TSH stimulation has fallen off and when many follicles are inactive and full of colloid (Figure 51.12).

Nodular goitre

Nodules are usually multiple, forming a multinodular goitre (Figure 51.13). Occasionally, only one macroscopic nodule is found, but microscopic changes will be present throughout the gland; this is one form of a clinically solitary nodule. Nodules may be colloid or cellular, and cystic degeneration and haemorrhage are common, as is subsequent calcification. Nodules appear early in endemic goitre and later (between 20 and 30 years) in sporadic goitre, although the patient may be unaware of the goitre until his or her late 40s or 50s. All types of simple goitre are more common in the female than in the male owing to the presence of oestrogen receptors in thyroid tissue.

Diagnosis

Diagnosis is usually straightforward. The patient is euthyroid, the nodules are palpable and often visible; they are smooth, usually firm and not hard, and the goitre is painless and moves freely on swallowing. Hardness and irregularity, due to calcification, may simulate carcinoma. A painful nodule, sudden appearance, or rapid enlargement of a nodule raises suspicion of carcinoma but is usually due to haemorrhage into a simple nodule. Differential diagnosis from autoimmune thyroiditis may be difficult and the two conditions frequently coexist.

Investigations

Thyroid function should be assessed to exclude mild hyperthyroidism, and the presence of circulating thyroid antibodies tested

Figure 51.12 Colloid goitre.

Figure 51.13 Large multinodular goitre.

to differentiate from autoimmune thyroiditis. Plain radiographs of the chest and thoracic inlet will rapidly demonstrate clinically significant tracheal deviation or compression. Ultrasound and CT give more detailed images but rarely influence clinical management. FNAC is only required for a dominant swelling in a generalised goitre.

Complications

Tracheal obstruction may be due to gross lateral displacement or

compression in a lateral or anteroposterior plane by retrosternal extension of the goitre (Figures 51.6 and 51.8). Acute respiratory obstruction may follow haemorrhage into a nodule impacted in the thoracic inlet.

Secondary thyrotoxicosis

Transient episodes of mild hyperthyroidism are common, occurring in up to 30 per cent of patients.

Carcinoma

An increased incidence of cancer (usually follicular) has been reported from endemic areas. Dominant or rapidly growing nodules in long-standing goitres should always be subjected to aspiration cytology.

Prevention and treatment of simple goitre

In endemic areas, e.g. Switzerland, parts of the USA and Argentina, the incidence of goitre has been strikingly reduced by the introduction of iodised salt.

In the early stages, a hyperplastic goitre may regress if thyroxine is given in a dose of 0.15–0.2 mg daily for a few months.

Although the nodular stage of simple goitre is irreversible, more than half of benign nodules will regress in size over ten years. Most patients with multinodular goitre are asymptomatic and do not require operation. Operation may be indicated on cosmetic grounds, for pressure symptoms or in response to patient anxiety. Retrosternal extension with actual or incipient tracheal compression is also an indication for operation, as is the presence of a dominant area of enlargement that may be neoplastic.

There is a choice of surgical treatment in multinodular goitre: **total thyroidectomy** with immediate and lifelong replacement of thyroxine, or some form of partial resection, to conserve sufficient functioning thyroid tissue to subserve normal function while reducing the risk of hypoparathyroidism that accompanies total thyroidectomy. **Subtotal thyroidectomy** involves partial resection of each lobe, removing the bulk of the gland, leaving up to 8 g of relatively normal tissue in each remnant. The technique is essentially the same as described for toxic goitre, as are the postoperative complications. More often, however, the multinodular change is asymmetrically distributed, with one lobe more significantly involved than the other. In these circumstances, particularly in older patients, **total lobectomy** on the more affected side is the appropriate management with either subtotal resection (Dunhill procedure) or no intervention on the less affected side. In many cases, the causative factors persist and recurrence is likely. Reoperation for recurrent nodular goitre is more difficult and hazardous and, for this reason, an increasing number of thyroid surgeons favour **total thyroidectomy** in younger patients. However, when the first operation comprised unilateral lobectomy alone for asymmetric goitre, reoperation and completion total thyroidectomy is straightforward if required for progression of nodularity in the remaining lobe. Total lobectomy and total thyroidectomy have the additional advantage of being therapeutic for incidental carcinomas (see below).

After subtotal resection, it has been customary to give thyroxine to suppress TSH secretion, with the aim of preventing recurrence. Whether this is either necessary or effective is uncertain, although the evidence of benefit in endemic areas is better than elsewhere. There is some evidence that radioactive iodine may reduce the size of recurrent nodular goitre after previous

subtotal resection and, in some circumstances, this may be a safer alternative than reoperation, particularly if there has been more than one previous thyroid procedure.

Clinically discrete swellings

Discrete thyroid swellings (thyroid nodules) are common and are present in 3–4 per cent of the adult population in the UK and USA. They are three to four times more frequent in women than men.

Diagnosis

A discrete swelling in an otherwise impalpable gland is termed **isolated** or **solitary**, whereas the preferred term is **dominant** for a similar swelling in a gland with clinical evidence of generalised abnormality in the form of a palpable contralateral lobe or generalised mild nodularity. About 70 per cent of discrete thyroid swellings are clinically isolated and about 30 per cent are dominant. The true incidence of isolated swellings is somewhat less than the clinical estimate. Clinical classification is inevitably subjective and overestimates the frequency of truly isolated swellings. When such a gland is exposed at operation or examined by ultrasonography, CT or MRI, clinically impalpable nodules are often detected. The true frequency of thyroid nodularity compared with the clinical detection rate by palpation is shown in Figure 51.14. Demonstrating the presence of impalpable nodules does not change the management of palpable discrete swellings and begs the question of the necessity of investigating incidentally found nodules. The importance of discrete swellings lies in the risk of neoplasia compared with other thyroid swellings. Some 15 per cent of isolated swellings prove to be malignant, and an additional 30–40 per cent are follicular adenomas. The remainder are non-neoplastic, largely consisting of areas of colloid degeneration, thyroiditis or cysts. Although the incidence of malignancy or follicular adenoma in clinically dominant swellings is approximately half of that of truly isolated swellings, it is substantial and cannot be ignored (Figure 51.15).

Investigation

Thyroid function

Serum TSH and thyroid hormone levels should be measured. If hyperthyroidism associated with a discrete swelling is confirmed biochemically, it indicates either a 'toxic adenoma' or a manifestation of toxic multinodular goitre. The combination of toxicity and nodularity is important and is an indication for isotope scanning to localise the area(s) of hyperfunction.

Figure 51.14 The prevalence of thyroid nodules detected on palpation (broken line) or by ultrasonography or post-mortem examination (solid line) (after Mazzaferri).

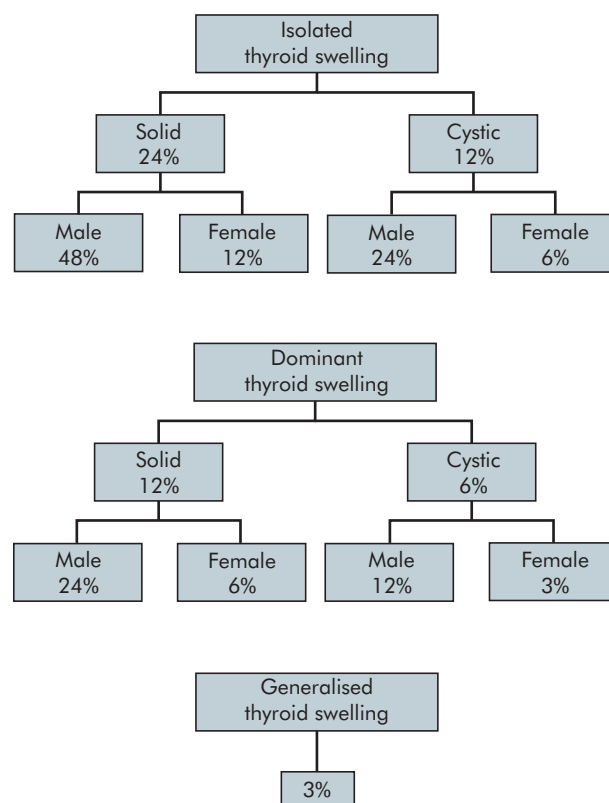

Figure 51.15 The risk of malignancy in thyroid swellings ('rule of twelve'). The risk of cancer in a thyroid swelling can be expressed as a factor of 12. The risk is greater in isolated versus dominant swellings, solid versus cystic swellings, and in men versus women.

Autoantibody titres

The autoantibody status may determine whether a swelling is a manifestation of chronic lymphocytic thyroiditis. The presence of circulating antibodies increases the risk of thyroid failure after lobectomy.

Isotope scan

Isotope scanning used to be the mainstay of investigation of discrete thyroid swellings to determine the functional activity relative to the surrounding gland according to isotope uptake.

On scanning, swellings are categorised as 'hot' (overactive), 'warm' (active) or 'cold' (underactive). A hot nodule is one that takes up isotope, while the surrounding thyroid tissue does not. Here the surrounding thyroid tissue is inactive because the nodule is producing such high levels of thyroid hormones that TSH secretion is suppressed (Figure 51.9). A warm nodule takes up isotope and so does normal thyroid tissue around it. A cold nodule takes up no isotope.

About 80 per cent of discrete swellings are cold, but only 15 per cent subsequently prove to be malignant and the use of this criterion as an indication for operation lacks discrimination. Routine isotope scanning has been abandoned except when toxicity is associated with nodularity.

Ultrasonography

This is widely used as a non-invasive supplement to clinical examination in determining the physical characteristics of

thyroid swellings. It can demonstrate subclinical nodularity and cyst formation, the former is clinically irrelevant and the latter apparent at aspiration, which should be routine in all discrete swellings. There are a number of ultrasonic features in a thyroid swelling associated with thyroid neoplasia, including microcalcification and increased vascularity, but only macroscopic capsular breach and nodal involvement are diagnostic of malignancy. As an adjunct to FNAC it can reduce the rate of unsatisfactory specimens and is invaluable in the mapping of malignant lymphadenopathy.

Fine-needle aspiration cytology

Fine-needle aspiration cytology is the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the outpatient department and is readily repeated.

Thyroid conditions that may be diagnosed by FNAC include colloid nodules (Figure 51.16), thyroiditis, papillary carcinoma (Figure 51.17), medullary carcinoma, anaplastic carcinoma and lymphoma. FNAC cannot distinguish between a benign follicular adenoma (Figure 51.18) and follicular carcinoma, as this distinction is dependent not on cytology but on histological criteria, which include capsular and vascular invasion.

Although FNAC was reported as highly accurate by Lowhagen and his colleagues (who were its pioneers) at the Karolinska Hospital, such high accuracy has not always been reproducible. There are very few false positives with respect to malignancy, but there is a definite false-negative rate with respect to both benign and malignant neoplasia. In addition, there can be a high rate of unsatisfactory aspirates, particularly in cystic or partly cystic swellings. These often yield only cyst fluid with macrophages and degenerate cells with few thyroid follicular cells upon which to report. After aspiration, a further sample for cytology should be taken from the cyst wall. There has been a recent trend to use ultrasound to guide the needle to achieve more accurate sampling and reduce the rate of unsatisfactory aspirates. Relatively few cysts are permanently abolished by one or more aspirations

and, because of the risk of malignancy, recurrent cysts should be removed.

Radiology

Chest and thoracic inlet radiographs may confirm tracheal deviation, compression or retrosternal extension and are required when either clinical suspicion or FNAC indicates malignancy.

Other scans

CT and MRI scans give excellent anatomical detail of thyroid swellings but have no role in the first line of investigation. They are most useful in assessing retrosternal (Figure 51.8) and recurrent swellings, particularly if initial surgery has been performed elsewhere. PET scan (Figure 51.19) may be useful, particularly in localising disease which does not take up radioiodine.

Laryngoscopy

Flexible laryngoscopy has rendered indirect laryngoscopy obsolete and is widely used preoperatively to determine the mobility of the vocal cords, although usually for medicolegal rather than clinical reasons. Nevertheless, the presence of a unilateral cord palsy coexisting with a swelling suggestive of malignancy is usually diagnostic.

Figure 51.16 Thy2 aspiration cytology. Non-neoplastic appearances with scanty normal follicular cells together with colloid (= colloid nodule).

Figure 51.19 Fused computed tomography and positron emission tomography scans showing left-sided thyroid neoplasm (courtesy of Dr M Brooks, Aberdeen, UK).

Core biopsy

Core biopsy gives a strip of tissue for histological rather than cytological assessment. It has a high diagnostic accuracy but requires local anaesthesia, and may be associated with complications such as pain, bleeding, tracheal and recurrent laryngeal nerve damage. It has little application in routine assessment except in locally advanced, surgically unresectable malignancy (either anaplastic carcinoma or lymphoma) when a core biopsy may obviate the need for an operative biopsy. In some centres core biopsy is recommended following FNAC when a Thy1 FNAC (inadequate cytology) specimen has been obtained to avoid operating where the risk of malignancy is very low. It is unlikely to be useful in differentiating benign from malignant Thy3 specimens (follicular lesions) as explained below.

Treatment

The main indication for operation is the risk of neoplasia, which includes follicular adenoma as well as malignant swellings. The reason for advocating the removal of all follicular neoplasms is that it is seldom possible to distinguish between a follicular adenoma and carcinoma cytologically. The distinction usually depends on histological evidence of capsular or vascular invasion and FNAC cannot make this distinction although, on occasion, cellular nuclear features may be so abnormal as to suggest malignant change. On this basis, some 50 per cent of isolated swellings and 25 per cent of dominant swellings should be removed on the grounds of neoplasia. Even when the cytology is negative, the age and sex of the patient and the size of the swelling may be relative indications for surgery, especially when a large swelling is responsible for symptoms. Some patients are happier to have a swelling removed even when cytology is negative.

There are useful clinical criteria to assist in selection for operation according to the risk of neoplasia and malignancy. Hard texture alone is not reliable as tense cystic swellings may be suspiciously hard but a hard, irregular swelling with any apparent fixity, which is unusual, is highly suspicious. Evidence of recurrent laryngeal nerve paralysis, suggested by hoarseness and a non-occlusive cough and confirmed by laryngoscopy, is almost pathognomonic. Deep cervical lymphadenopathy along the internal jugular vein in association with a clinically suspicious swelling is almost diagnostic of papillary carcinoma. In

most patients, however, such features are absent but there are risk factors associated with sex and age. The incidence of thyroid carcinoma in women is about three times that in men, but a discrete swelling in a male is much more likely to be malignant than in a female and it is seldom justifiable to avoid removing such a swelling in a man. The risk of carcinoma is increased at either end of the age range and a discrete swelling in a teenager of either sex must be provisionally diagnosed as carcinoma.

The risk increases as age advances beyond 50 years, more so in males.

Thyroid cysts

Routine FNAC (or ultrasonography) shows that over 30 per cent of clinically isolated swellings contain fluid and are cystic or partly cystic. Tense cysts may be hard and mimic carcinoma. Bleeding into a cyst often presents with a history of sudden painful swelling, which resolves to a variable extent over a period of weeks if untreated. Aspiration yields altered blood but reaccumulation is frequent. About 50 per cent of cystic swellings are the result of colloid degeneration, or of uncertain aetiology, because of an absence of epithelial cells in the lining. Although most of the remainder are the result of involution in follicular adenomas (Figure 51.20), some 10–15 per cent of cystic follicular swellings are histologically malignant (30 per cent in men and 10 per cent in women). Papillary carcinoma is often associated with cyst formation (Figure 51.21).

Most patients with discrete swellings, however, are women, aged 20–40 years, in whom the risk of malignancy, although significant, is low and the indications for operation are not clear-cut. FNAC is the most appropriate investigation to aid selection.

The indications for operation in isolated or dominant thyroid swellings are listed in Table 51.5.

Selection of thyroid procedure

The choice of thyroid operation depends on:

- diagnosis (if known preoperatively);
- risk of thyroid failure;
- risk of recurrent laryngeal nerve injury;
- risk of recurrence;
- Graves' disease;
- multinodular goitre;
- differentiated thyroid cancer;
- risk of hypoparathyroidism.

Total and near-total thyroidectomy do not conserve sufficient thyroid tissue for normal thyroid function and thyroid replacement therapy is necessary. In most patients with negative antithyroid antibodies, one thyroid lobe will maintain normal function. In subtotal thyroidectomy, the volume of thyroid tissue preserved influences the risk of thyroid failure and larger remnants have a better chance of normal function but a higher risk of recurrence in Graves' disease.

Subtotal resections for colloid goitre run the risk of later growth of the remnant and, if a second operation is required years later, this greatly increases the risk to the RLN and parathyroids. In young patients, total thyroidectomy should be

considered. It may be preferable to leave the least affected lobe untouched to permit a straightforward lobectomy in the future if required, rather than carry out subtotal resections.

In Graves' disease, preserving large remnants increases the risk of recurrence of the toxicity and, in these cases, it is better to err on the side of removing too much thyroid tissue rather than too little (Table 51.6). Thyroid failure need not be regarded as a failure of treatment but recurrent toxicity is.

The relative merits of routine total versus selective total thyroidectomy in differentiated thyroid cancer are discussed below (Summary box 51.4).

Summary box 51.4

Thyroid operations

All thyroid operations can be assembled from three basic elements:

- 1 Total lobectomy
- 2 Isthmusectomy
- 3 Subtotal lobectomy

Total thyroidectomy = 2 × total lobectomy + isthmusectomy

Subtotal thyroidectomy = 2 subtotal lobectomy + isthmusectomy

Near-total thyroidectomy = total lobectomy + isthmusectomy + subtotal lobectomy (Dunhill procedure)

Lobectomy = total lobectomy + isthmusectomy

Retrosternal goitre

Very few retrosternal goitres arise from ectopic thyroid tissue; most arise from the lower pole of a nodular goitre. If the neck is short and the pretracheal muscles are strong, as in men, the negative intrathoracic pressure tends to draw these nodules into the superior mediastinum.

Clinical features

A retrosternal goitre is often symptomless and discovered on a routine chest radiograph (Figure 51.6). There may, however, be severe symptoms:

Robert James Graves, 1796–1853, physician, Meath Hospital, Dublin, Ireland, published an account of exophthalmic goitre in 1835. He was President of the Royal College of Physicians of Ireland and elected Fellow of The Royal Society of London in 1849. There is a statue of him in the Royal College of Physicians in Ireland.

Table 51.6 Comparison of surgical options for Graves' disease.

	Total thyroidectomy	Subtotal thyroidectomy
Control of toxicity	Immediate	Immediate
Return to euthyroid state	Immediate	Variable – up to 12 months
Risk of recurrence	None	Lifelong – up to 5% ^a
Risk of thyroid failure	100%	Lifelong – up to 100% at 30 years ^a
Risk of permanent hypoparathyroidism	5%	1%
Need for follow up	Minimal	Lifelong

^aThe risk of recurrence and late failure are a function of the size of the remnant as a proportion of the total gland weight. Large remnants in small glands have a higher risk of recurrence and a low risk of failure, and small remnants in large glands have a higher risk of thyroid failure but a low risk of recurrence.

Figure 51.22 Retrosternal goitre with superior vena cava obstruction. (a) Preoperative appearance showing venous congestion. (b) Sternal split to deliver impacted left thyroid lobe. The recurrent laryngeal nerve is visible. (c) Postoperative appearance.

- Dyspnoea, particularly at night, cough and stridor (harsh sound on inspiration). Many patients attend a chest clinic with a diagnosis of asthma before the true nature of the problem is discovered.
- Dysphagia.
- Engorgement of facial, neck and superficial chest wall veins; in severe cases there may be obstruction of the superior vena cava (Figure 51.22).
- Recurrent nerve paralysis is rare; the goitre may also be malignant or toxic.

Chest and thoracic inlet radiographs show a soft-tissue shadow in the superior mediastinum, sometimes with calcification, and often causing deviation and compression of the trachea. CT scan gives the most accurate and, often dramatic, anatomical visualisation (Figure 51.8).

Significant tracheal compression and obstruction may be demonstrated objectively by a flow-volume loop pulmonary function test in which the rate of flow is plotted against the volume of air inspired and then expired. Deterioration in flow due to increase in tracheal compression, either acutely or in the long term, may be used to monitor progression of the disease and indicate the need for surgery. The changes are reversed by operation (Figure 51.23).

Treatment

If obstructive symptoms are present in association with thyrotoxicosis it is unwise to treat a retrosternal goitre with antithyroid drugs or radioiodine as these may enlarge the goitre. Resection can almost always be carried out from the neck, but median sternotomy is sometimes necessary (Figure 51.22b). The cervical part of the goitre should first be mobilised following division of the superior thyroid vessels and middle thyroid vein. Early division of the isthmus is often helpful. The retrosternal goitre can then be delivered by traction, which may be facilitated by inserting a series of sutures, finger or, traditionally, a spoon. Haemorrhage is rarely a problem because the goitre takes its blood supply with it from the neck. The recurrent laryngeal nerve should be identified before delivering the retrosternal goitre, as it may be abnormally displaced and is particularly vulnerable to injury from traction or tearing. If a large retrosternal goitre cannot be delivered intact, piecemeal delivery is possible but risks leaving a fragment of nodular goitre deep in the mediastinum resulting in

Figure 51.23 Flow-volume loops before and after operation on a goitre causing tracheal obstruction.

a very difficult reoperation many years later. Fragmentation must be avoided when malignancy is likely and all these problems are avoided with a timely median sternotomy.

Thyroid incidentaloma

The increased use of imaging modalities for non-thyroid head and neck pathology has created the clinical conundrum of the 'thyroid incidentaloma'. These are clinically unsuspected and impalpable thyroid swellings and, in some parts of the world, have reached 'epidemic' proportions. Injudicious reporting generates needless anxiety if the possibility of malignancy is raised inappropriately. The vast majority of impalpable thyroid swellings can be safely managed expectantly by a single annual review, with no intervention unless certain criteria are met or the swelling becomes palpable (Figure 51.24).

HYPERTHYROIDISM

Thyrotoxicosis

The term thyrotoxicosis is retained because hyperthyroidism, i.e. symptoms due to a raised level of circulating thyroid hormones, is not responsible for all manifestations of the disease. Clinical types are:

- diffuse toxic goitre (Graves' disease);
- toxic nodular goitre;
- toxic nodule;
- hyperthyroidism due to rarer causes.

Diffuse toxic goitre

Graves' disease, a diffuse vascular goitre appearing at the same time as the hyperthyroidism, usually occurs in younger women and is frequently associated with eye signs. The syndrome is that of primary thyrotoxicosis (Figure 51.25); 50 per cent of patients have a family history of autoimmune endocrine diseases. The whole of the functioning thyroid tissue is involved, and the hypertrophy and hyperplasia are due to abnormal thyroid-

Figure 51.25 Graves' disease.

stimulating antibodies (TSH-RAb) that bind to TSH receptor sites and produce a disproportionate and prolonged effect.

Toxic nodular goitre

A simple nodular goitre is present for a long time before the hyperthyroidism, usually in the middle-aged or elderly, and very infrequently is associated with eye signs. The syndrome is that of secondary thyrotoxicosis.

In many cases of toxic nodular goitre, the nodules are inactive, and it is the internodular thyroid tissue which is overactive. However, in some toxic nodular goitres, one or more nodules are overactive and here the hyperthyroidism is due to autonomous thyroid tissue as in a toxic adenoma.

Toxic nodule

A toxic nodule is a solitary overactive nodule, which may be part of a generalised nodularity or a true toxic adenoma. It is autonomous and its hypertrophy and hyperplasia are not due to TSH-RAb. TSH secretion is suppressed by the high level of circulating thyroid hormones and the normal thyroid tissue surrounding the nodule is itself suppressed and inactive.

Histology

The normal thyroid gland consists of acini lined with flattened cuboidal epithelium and filled with homogeneous colloid (Figure 51.3). In hyperthyroidism (Figure 51.26), there is hyperplasia of acini, which are lined by high columnar epithelium. Many of them are empty, and others contain vacuolated colloid with a characteristic 'scalloped' pattern adjacent to the thyrocytes.

Clinical features

The symptoms are:

- tiredness
- emotional lability
- heat intolerance
- weight loss
- excessive appetite
- palpitations.

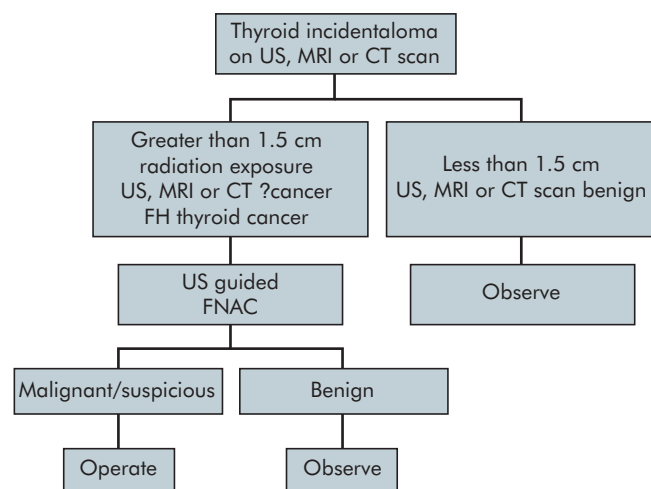

Figure 51.24 Management of thyroid incidentalomas. CT, computed tomography; FH, family history; FNAC, fine-needle aspiration cytology; MRI, magnetic resonance imaging; US, ultrasound.

Figure 51.26 Histology of thyrotoxicosis.

The signs of thyrotoxicosis are:

- tachycardia
- hot, moist palms
- exophthalmos
- eyelid lag/retraction
- agitation
- thyroid goitre and bruit.

Symptomatology

Thyrotoxicosis is eight times more common in women than in men. It may occur at any age. The most significant symptoms are loss of weight despite a good appetite, a recent preference for cold, and palpitations. The most significant signs are the excitability of the patient, the presence of a goitre, exophthalmos and tachycardia or cardiac arrhythmia.

The goitre in primary thyrotoxicosis is diffuse and vascular; it may be large or small, firm or soft, and a thrill and a bruit may be present. The onset is abrupt, but remissions and exacerbations are not infrequent. Hyperthyroidism is usually more severe than in secondary thyrotoxicosis but cardiac failure is rare. Manifestations of thyrotoxicosis not due to hyperthyroidism per se, for example orbital proptosis, ophthalmoplegia and pretibial myxoedema, may occur in primary thyrotoxicosis.

In secondary thyrotoxicosis, the goitre is nodular. The onset is insidious and may present with cardiac failure or atrial fibrillation. It is characteristic that the hyperthyroidism is not severe. Eye signs other than lid lag and lid spasm (due to hyperthyroidism) are very rare.

Cardiac rhythm

A fast heart rate, which persists during sleep, is characteristic. Cardiac arrhythmias are superimposed on the sinus tachycardia as the disease progresses, and they are more common in older patients with thyrotoxicosis because of the prevalence of coincidental heart disease. Stages of development of thyrotoxic arrhythmias are:

- 1 multiple extrasystoles
- 2 paroxysmal atrial tachycardia
- 3 paroxysmal atrial fibrillation
- 4 persistent atrial fibrillation, not responsive to digoxin.

Myopathy

Weakness of the proximal limb muscles is commonly found if looked for. Severe muscular weakness (thyrotoxic myopathy), resembling myasthenia gravis, occurs occasionally. Recovery proceeds as hyperthyroidism is controlled.

Eye signs

Some degree of exophthalmos is common (Figure 51.25). It may be unilateral. True exophthalmos is a proptosis of the eye, caused by infiltration of the retrobulbar tissues with fluid and round cells, with a varying degree of retraction or spasm of the upper eyelid. (Lid spasm occurs because the levator palpebrae superioris muscle is partly innervated by sympathetic fibres.) This results in widening of the palpebral fissure so that the sclera may be seen clearly above the upper margin of the iris and cornea (above the 'limbus').

Spasm and retraction usually disappear when the hyperthyroidism is controlled. They may be improved by beta-adrenergic blocking drugs, for example guanethidine eye drops. Oedema of the eyelids, conjunctival injection and chemosis are aggravated by compression of the ophthalmic veins (Figure 51.27). Weakness of the extraocular muscles, particularly the elevators (inferior oblique), results in diplopia. In severe cases, papilloedema and corneal ulceration occur. When severe and progressive, it is known as malignant exophthalmos (Figure 51.28) and the eye may be destroyed. Graves' ophthalmopathy is an autoimmune disease in which there are antibody-mediated effects on the ocular muscles.

Exophthalmos tends to improve with time. Sleeping propped up and lateral tarsorrhaphy will help to protect the eye but will not prevent progression. Hypothyroidism increases proptosis by a few millimetres and should be avoided.

Improvement has been reported with massive doses of prednisone. Intraorbital injection of steroids is dangerous because of the venous congestion, and total thyroid ablation has not proved effective. When the eye is in danger, orbital decompression may be required (see Orbital swellings in Chapter 44).

Thyroid dermopathy ('pretibial myxoedema') (Figure 51.29) is a rare condition characterised by thickening of the skin, usually in areas of trauma, by deposition of hyaluronic acid in the dermis and subcutis. It usually occurs a few years after the onset of thyrotoxicosis and usually responds to treatment of the underlying thyroid disorder and topical steroids.

Figure 51.28 (a) Progressive (malignant) exophthalmos. (b) Following treatment with steroids, orbital radiotherapy and bilateral tarsorrhaphy (courtesy of Professor JS Bevan, Aberdeen, UK).

Diagnosis of thyrotoxicosis

Most cases are readily diagnosed clinically. Difficulty is most likely to arise in the differentiation of mild hyperthyroidism from an anxiety state when a goitre is present. In these cases, the thyroid status is determined by the diagnostic tests described earlier. A TRH test is rarely indicated.

T_3 thyrotoxicosis is diagnosed by estimating the free T_3 . It should be suspected if the clinical picture is suggestive but routine tests of thyroid function reveal a normal T_4 but suppressed TSH. A thyroid scan is required to diagnose an autonomous toxic nodule (Figure 51.8) and differentiate it from a dominant swelling in a toxic multinodular goitre.

Thyrotoxicosis should always be considered in:

- children with a growth spurt, behaviour problems or myopathy;
- tachycardia or arrhythmia in the elderly;
- unexplained diarrhoea;
- loss of weight.

Principles of treatment of thyrotoxicosis

Non-specific measures are rest and sedation and in established thyrotoxicosis should be used only in conjunction with specific measures, i.e. the use of antithyroid drugs, surgery and radio-iodine.

Figure 51.29 Thyroid dermopathy (pretibial myxoedema). It is usually symmetrical, and minor degrees are not uncommon but are easily missed. The earliest stage is a shiny red plaque of thickened skin with coarse hair, which may be cyanotic when cold. In severe cases, the skin of the whole leg below the knee is involved, together with that of the foot and the ankle, and there may be clubbing of the fingers and toes (thyroid acropachy).

Antithyroid drugs

Those in common use are carbimazole and propylthiouracil. β -Adrenergic blockers, such as propranolol and nadolol, are used to block the cardiovascular effects of the elevated T_4 . Iodides, which may reduce the vascularity of the thyroid, should only be used as immediate preoperative preparation in the 10 days before surgery. Antithyroid drugs are used to restore the patient to a euthyroid state and to maintain this for a prolonged period in the hope that a permanent remission will occur, i.e. that production of thyroid-stimulating antibodies (TSH-RAb) will diminish or cease. Antithyroid drugs cannot cure a toxic nodule. The overactive thyroid tissue is autonomous and recurrence of the hyperthyroidism is certain when the drug is discontinued.

- **Advantages.** No surgery and no use of radioactive materials.
- **Disadvantages.** Treatment is prolonged and the failure rate is at least 50 per cent. The duration of treatment may be tailored to the severity of the toxicity with milder cases being treated for only six months and severe for two years before stopping therapy.

It is impossible to predict which patient is likely to go into permanent remission although large gland size, severity of disease and TSH-RAb levels are indicators of poor prognosis.

Some goitres enlarge and become very vascular during treatment, even if thyroxine is given at the same time. This is probably due to TSH-RAb stimulation during the prolonged course of treatment and not a direct effect of the drug.

Very rarely, there is a dangerous drug reaction, particularly agranulocytosis or aplastic anaemia. If a sore throat develops, the patient should be instructed to discontinue treatment, until

the white cell count has been checked because of the risk of agranulocytosis.

Initially, 10 mg of carbimazole is given three or four times a day, with a latent interval of 7–14 days before clinical improvement is apparent. It is important to maintain a high concentration of the drug throughout the 24 hours by spacing the doses at 8- or 6-hourly intervals. When the patient becomes biochemically euthyroid, a maintenance dose of 5 mg two or three times a day is given for 6–24 months. An alternative technique is to continue with the high dose of carbimazole and inhibit all T_3 and T_4 production then giving a maintenance dose of 0.1–0.15 mg of thyroxine daily. There is no risk of producing iatrogenic thyroid insufficiency and follow up is less demanding ('block and replacement treatment').

The levels of TSH-RAb usually fall during treatment and this accounts for the permanent cure that occurs in 50 per cent of patients.

Surgery

In diffuse toxic goitre and toxic nodular goitre with overactive internodular tissue, surgery cures by reducing the mass of overactive tissue. Surgery achieves a cure by reducing the thyroid below a critical mass. After subtotal thyroidectomy the patient should return to a euthyroid state, albeit after a variable period of hypothyroidism. There are, however, the long-term risks of recurrence and eventual thyroid failure. In contrast, total/near total thyroidectomy accepts immediate thyroid failure and life-long thyroxine replacement to eliminate the risk of recurrence and simplify follow up. Operation may result in a reduction in TSH-RAb. In the autonomous toxic nodule, and in toxic nodular goitre with overactive autonomous toxic nodules, surgery cures by removing all the overactive thyroid tissue: this allows the suppressed normal tissue to function again.

- **Advantages.** The goitre is removed, the cure is rapid, and the cure rate is high if surgery has been adequate.
- **Disadvantages.** Recurrence of thyrotoxicosis occurs in approximately 5 per cent of cases when subtotal thyroidectomy is carried out. There is a risk of permanent hypoparathyroidism and nerve injury. Young women tend to have a poorer cosmetic result from the scar.

Every operation carries a risk, but with suitable preparation and an experienced surgeon the mortality is negligible and the morbidity low.

After subtotal resection thyroid failure is almost universal by 30 years although a few patients can develop recurrent toxicity many years after surgery. Long-term follow up is necessary to detect and treat both.

The incidence of permanent parathyroid insufficiency should be less than 5 per cent.

Radioiodine

Radioiodine destroys thyroid cells and, as in thyroidectomy, reduces the mass of functioning thyroid tissue to below a critical level.

- **Advantages.** No surgery and no prolonged drug therapy.
- **Disadvantages.** Isotope facilities must be available. The patient must be quarantined while radiation levels are high and avoid pregnancy and close physical contact, particularly with children. Eye signs may be aggravated.

The rate and timing of late thyroid failure are influenced by the dose selected (200–600 MBq). The higher dose is likely to result in thyroid failure in six months, whereas the lower dose may result in insufficiency which may reach a rate of 75–80 per cent after ten years. This is due to sublethal damage to those cells not actually destroyed by the initial treatment and this eventually causes failure of cellular reproduction. Indefinite follow up is essential.

There is no evidence that therapeutic radioiodine is carcinogenic or teratogenic. In some clinics, radioiodine is given to almost all patients including children. Response is slow, but a substantial improvement is to be expected in 8–12 weeks. Accurate dosage is difficult and, should there be no clinical improvement after 12 weeks, a further dose is given. Two or more doses are necessary in 20–30 per cent of cases. Follow-up requirements are reduced if a larger ablative dose of radioiodine is administered followed by routine replacement treatment with thyroxine.

Choice of therapy

Each case must be considered individually. Below are listed guiding principles on the most satisfactory treatment for a particular toxic goitre at a particular age; these must, however, be modified according to the facilities available and the personality, intelligence and wishes of the individual patient, business or family commitments and any other coexistent medical or surgical condition. Access to post-treatment care and availability of replacement thyroxine can be important considerations in the Third World.

In advising treatment, compliance, influenced by social and intellectual factors, is important; many patients cannot be trusted to take drugs regularly if they feel well, and indefinite follow up, which is essential after radioiodine or subtotal thyroidectomy, is a burden for all.

Diffuse toxic goitre

Most patients have an initial course of antithyroid drugs with radioiodine for relapse. Exceptions are those who refuse radiation, have large goitres, progressive eye signs or are pregnant.

Toxic nodular goitre

Toxic nodular goitre is often large and uncomfortable and enlarges still further with antithyroid drugs. A large goitre should be treated surgically because it does not respond as well or as rapidly to radioiodine or antithyroid drugs as does a diffuse toxic goitre.

Toxic nodule

Surgery or radioiodine treatment is appropriate. Resection is easy, certain and without morbidity. Radioiodine is a good alternative over the age of 45 years because the suppressed thyroid tissue does not take up iodine and there is thus no risk of delayed thyroid insufficiency.

Recurrent thyrotoxicosis after surgery

In general, radioiodine is the treatment of choice, but antithyroid drugs may be used in young women intending to have children. Further surgery has little place.

Failure of previous treatment with antithyroid drugs or radioiodine

In this case, surgery or thyroid ablation with ^{123}I is appropriate.

Special problems in treatment

Pregnancy

Radioiodine is absolutely contraindicated because of the risk to the fetus. The danger of surgery is miscarriage and the danger of antithyroid drugs is of inducing thyroid insufficiency in the mother and, because both TSH and antithyroid drugs cross the placenta, of the baby being born goitrous (Figure 51.30) and hypothyroid. The risk of either surgery in the second trimester, in competent hands, or careful administration of antithyroid drugs is very small and the choice is exactly as in the uncomplicated case.

Postpartum hyperthyroidism

Pregnancy may lead to an exacerbation of a variety of autoimmune diseases in the postpartum period. Postpartum hyperthyroidism may be a problem in a patient previously diagnosed with hyperthyroidism or may occur in a patient without any previous history of thyroid disease.

Children

Radioiodine is relatively contraindicated because of the theoretical risk of inducing thyroid carcinoma. There is an increased risk of recurrence after thyroidectomy because thyroid cells are highly active in the young. Children and adolescents should be treated with anti-thyroid drugs until the late teens, failing which total or near-total thyroidectomy by an expert surgeon should be undertaken.

The thyrocardiac

This is a patient with severe cardiac damage due wholly or partly to hyperthyroidism. The patient is usually middle aged or elderly with secondary thyrotoxicosis and the hyperthyroidism is not very severe: untreated Graves' disease sufficient to produce the level of emaciation and cardiomyopathy is rare in contemporary Western practice. The cardiac condition is far more significant

than the hyperthyroidism, but this must be rapidly controlled to prevent further cardiac damage. Beta-blockade (propranolol or nadolol) can assist rapid control of cardiac effects.

Radioiodine is the treatment of choice together with antithyroid drugs started either before or after and continued until the radioiodine has had effect (usually 6 weeks).

High titres of thyroid antibodies

Their presence indicates lymphatic infiltration of the goitre, i.e. a diffuse or focal thyroiditis, and a liability to spontaneous remission.

These patients are best treated with antithyroid drugs but if medical treatment fails, definitive treatment by operation or radioiodine is not contraindicated. Steroids may help to reduce pain and swelling.

Proptosis of recent onset

There is a conventional view that to terminate thyrotoxicosis abruptly by thyroidectomy or radioiodine when proptosis is recent may induce malignant exophthalmos. Although there is no real proof of this, it is reasonable to treat these patients with antithyroid drugs until the proptosis has been static for six months.

Hyperthyroidism due to other causes

Thyrotoxicosis factitia

Hyperthyroidism may be induced by taking thyroxine, but only if the dosage exceeds the normal requirements of 0.15–0.25 mg per day. Doses below the normal requirements simply suppress normal hormone production by the thyroid.

Jod-Basedow thyrotoxicosis

In European countries, diffuse toxic goitre is often called Basedow's disease or Jod-Basedow thyrotoxicosis (jod = German for iodine + Basedow). Large doses of iodide given to a patient with a hyperplastic endemic goitre that is iodine avid may produce temporary hyperthyroidism and, very occasionally, persistent hyperthyroidism.

Subacute/acute forms of autoimmune thyroiditis or of de Quervain's thyroiditis

In subacute or acute forms of autoimmune thyroiditis or of de Quervain's thyroiditis (see later), mild hyperthyroidism may occur in the early stages due to liberation of thyroid hormones from damaged tissue.

Secondary carcinoma

A large mass of secondary carcinoma will rarely produce sufficient hormone to induce mild hyperthyroidism.

Neonatal thyrotoxicosis

Neonatal thyrotoxicosis occurs in babies born to hyperthyroid mothers or to euthyroid mothers who have had thyrotoxicosis. High TSH-RAb titres are present in both mother and child because TSH-RAb can cross the placental barrier. The hyperthyroidism gradually subsides in 3–4 weeks time as the TSH-RAb titres fall in the baby's serum.

Figure 51.30 Transmitted thiouracil goitre. This does not occur if T_3 is given with antithyroid drugs, as it too crosses the placenta.

The soil of New Zealand is heavily impregnated with **iodine**, but this does not prevent goitre in man, sheep and other animals (Sir Charles Hercus, former Professor of Public Health, University of Otago, New Zealand).

Surgery for thyrotoxicosis

Preoperative preparation

Traditional preparation aims to make the patient biochemically euthyroid at operation. The thyroid state is determined by clinical assessment, i.e. by improvement in previous symptoms and by objective signs such as weight gain and lowering of the pulse rate, and by serial estimations of the thyroid profile.

Preparation is as an outpatient and only rarely is admission to hospital necessary on account of severe symptoms at presentation, failure to control the hyperthyroidism or non-compliance with medication. Failure to control with antithyroid drugs is unusual but may be due to uneven dosage, i.e. not taking the drug at 6- or 8-hourly intervals.

Carbimazole 30–40 mg per day is the drug of choice for preparation. When euthyroid (after 8–12 weeks), the dose may be reduced to 5 mg 8-hourly or a 'block and replace' regime used (see above). The last dose of carbimazole may be given on the evening before surgery. Iodides are not used alone because, if the patient needs preoperative treatment, a more effective drug should be given.

An alternative method of preparation is to abolish the clinical manifestations of the toxic state, using β -adrenergic blocking drugs. These act on the target organs and not on the gland itself. Propranolol also inhibits the peripheral conversion of T_4 to T_3 . The appropriate dosages are propranolol 40 mg three times a day or the longer-acting nadolol 160 mg once daily. Clinical response to beta-blockade is rapid and the patient may be rendered clinically euthyroid and operation arranged in a few days rather than weeks. The dose of β -adrenergic blocking drug is increased to achieve the required clinical response and quite often larger doses (propranolol 80 mg three times a day or nadolol 320 mg once daily) are necessary.

β -Adrenergic blocking drugs do not interfere with synthesis of thyroid hormones, and hormone levels remain high during treatment and for some days after thyroidectomy. It is, therefore, important to continue to give the drug for 7 days postoperatively.

Iodine may be given with carbimazole or a β -adrenergic blocking drug for the 10 days before operation. Iodide alone produces a transient remission and may reduce vascularity, thereby marginally improving safety. The use of iodine preparations is not universal because of more effective alternatives. Iodine gives an additional measure of safety in case the early morning dose of β -adrenergic blocking drug is mistakenly omitted on the day of operation.

Surgery

Preoperative investigations to be carried out and recorded are:

- **Thyroid function tests.**
- **Laryngoscopy.** Whether this is routine is a matter for local protocols. The outcome should have little impact on the operation because every recurrent laryngeal nerve must be routinely and obsessively preserved.
- **Thyroid antibodies.**
- **Serum calcium estimation.**
- An **isotope scan** before preoperative preparation is necessary in patients with toxic nodular goitre if total thyroidectomy is not planned.

The extent of the resection depends on the size of the gland, the age of the patient, the experience of the surgeon, the need

to minimise the risk of recurrent toxicity and the wish to avoid postoperative thyroid replacement (Table 51.6).

Technique

General anaesthesia with endotracheal intubation and muscle relaxation is routine. The patient is supine on the operating table with the table tilted up 15° at the head end to reduce venous engorgement (reverse Trendelenburg). A gel pad or sandbag is placed transversely under the shoulders and the neck is extended (with care particularly in the elderly) to make the thyroid gland more prominent and apply tension to skin, platysma and strap muscles, which makes dissection easier.

A gently curved skin crease incision is made midway between the notch of the thyroid cartilage and the suprasternal notch: a lower incision is easier to hide but is more likely to result in a hypertrophic scar. Flaps of skin, subcutaneous tissue and platysma are raised upwards to the superior thyroid notch and downwards to the suprasternal notch. The deep cervical fascia is divided in the midline between the sternothyroid muscles down to the plane of the thyroid capsule. The strap muscles are not divided as a routine but may be if greater exposure is required. The sternothyroid muscle is mobilised off the thyroid lobes, taking care to stay close to the muscle and outside the capsule.

In 30 per cent of patients, middle thyroid veins passing directly into the internal jugular vein require ligation and division. The plane between the medial aspect of the upper pole and the cricothyroid muscle is developed by keeping close to the thyroid to minimise the risk of trauma to the external branch of the superior laryngeal nerve. The branches of the superior thyroid artery splay out over the upper pole and the author's preference is to ligate these individually. This permits progressive downward delivery of even the highest upper pole. The lobe is then free to rotate medially out of its bed. The inferior thyroid arteries are not routinely ligated to preserve parathyroid blood supply.

The recurrent laryngeal nerve should be identified in its course in the operative field. It should first be sought below the level of the inferior thyroid artery as it passes obliquely upwards and forwards on the right (Figure 51.31) but parallel to the tracheo-oesophageal groove on the left. If not immediately seen, the nerve can usually be palpated as a taut strand crossing the tracheo-oesophageal groove. At a higher level, the nerve lies between the branches of the inferior thyroid artery. The nerve

Figure 51.31 Identification of the recurrent laryngeal nerve (see text). Note how rotating the gland medially anteriorly kinks the nerve that is normally intimately related to the terminal branches of the inferior thyroid artery.

passes into the larynx under the inferior border of the inferior constrictor immediately behind the inferior cornu of the thyroid cartilage. If the right nerve cannot be found in its usual course, an anomalous (non-recurrent) nerve, present in 1 per cent of cases, should be suspected; this arises from the vagus trunk and usually passes from behind the carotid sheath, curving medially, forwards and upwards and may be mistaken for the inferior thyroid artery (Figure 51.32).

The parathyroid glands are identified by careful inspection in the common sites (Figure 51.4). The thymus is detached by serially dividing the inferior thyroid veins.

In subtotal thyroidectomy the isthmus is transected and the lobe resected obliquely from the medial and lateral aspects to produce a V-shaped surface (Figure 51.33). This facilitates subsequent suture of the divided surface for haemostasis. Care is required to avoid devascularisation of the parathyroids and damage to the recurrent laryngeal nerves particularly from the medial aspect. If a parathyroid gland is inadvertently or unavoidably excised or devascularised, it should be fragmented and autotransplanted immediately within the sternomastoid muscle.

Subtotal resection of each lobe is carried out, leaving a remnant of 4–5 g on each side. Absolute haemostasis is secured by ligation of individual vessels and by suture of the thyroid remnants to the tracheal fascia.

Total thyroidectomy (Figure 51.11) avoids transection of thyroid tissue by complete excision of the gland including the pyramidal lobe with preservation *in situ* or autotransplantation of as many parathyroids as can be identified.

The pretracheal muscles and cervical fascia are sutured and the wound closed. Randomised clinical trials have confirmed that routine drainage to the deep cervical space is not required.

New technology in thyroidectomy

The major immediate risk following thyroidectomy is haemorrhage and conventionally artery forceps, ligature and suture have been used to secure the meticulous haemostasis necessary to minimise the frequency. Ultrasonic shears and enhanced bipolar diathermy are increasingly used in thyroid surgery and may be advantageous in complex procedures. Identification of the RLN by electrical stimulation is popular in some centres but has no measurable impact on the incidence of RLN injury.

Figure 51.32 Operative photograph of non-recurrent laryngeal nerve (arrow). The inferior thyroid artery, as is often the case, is absent.

Figure 51.33 Technique of division of the mobilised thyroid lobe after division of the isthmus. The V-shaped resection margin facilitates subsequent suturing.

Postoperative complications

Haemorrhage

A tension haematoma deep to the cervical fascia is usually due to reactionary haemorrhage from one of the thyroid arteries; occasionally, haemorrhage from a thyroid remnant or a thyroid vein may be responsible. This is a rare but desperate emergency which requires urgent decompression by opening the layers of the wound, not simply the skin closure, to relieve tension before urgent transfer to theatre to secure the bleeding vessel (Figure 51.34).

A subcutaneous haematoma or collection of serum may form under the skin flaps and require evacuation in the following 48 hours. This should not be confused with the potentially life-threatening deep tension haematoma.

Figure 51.34 Postoperative haematoma. Subplatysmal haematoma may need evacuating (light grey) but tension haematoma (dark grey) deep to strap muscles requires urgent decompression and haemostasis.

Respiratory obstruction

This is very rarely due to collapse or kinking of the trachea (tracheomalacia). Most cases are due to laryngeal oedema. The most important cause of laryngeal oedema is a tension haematoma. However, trauma to the larynx by anaesthetic intubation and surgical manipulation are important contributory factors, particularly if the goitre is very vascular, and may cause laryngeal oedema without a tension haematoma. Unilateral or bilateral recurrent nerve paralysis will not cause immediate postoperative respiratory obstruction unless laryngeal oedema is also present, but will aggravate the obstruction.

If releasing a tension haematoma does not immediately relieve airway obstruction, the trachea should be intubated at once. An endotracheal tube can be left in place for several days; steroids are given to reduce oedema and a tracheostomy is rarely necessary. Intubation in the presence of laryngeal oedema may be very difficult and should be carried out by an experienced anaesthetist. Repeated unsuccessful attempts may aggravate the problem and, in a crisis, it is safer to perform a needle tracheostomy as a temporary measure; a large bore 12G intravenous cannula (diameter 2.3 mm) is satisfactory (see Emergency airway measures in Chapter 48).

Recurrent laryngeal nerve paralysis and voice change

Recurrent laryngeal nerve injury may be unilateral or bilateral, transient or permanent. Early routine postoperative laryngoscopy reveals a much higher incidence of transient cord paralysis than is detectable by simple assessment of the integrity of the voice and cough. Such temporary dysfunction is not clinically important however, but voice and cord function should be assessed at first follow up 4 weeks postoperatively. The British Association of Endocrine Surgeons audit revealed a RLN palsy rate of 1.8 per cent at one month declining to 0.5 per cent at three months for first-time operations. Permanent paralysis is rare if the nerve has been identified at operation. Injury to the external branch of the superior laryngeal nerve is more common because of its proximity to the superior thyroid artery. This leads to loss of tension in the vocal cord with diminished power and range in the voice. Patients, particularly those who use their voice professionally, must be advised that any thyroid operation will result in change to the voice even in the absence of nerve trauma. Fortunately, for most patients, the changes are subtle and only demonstrable on formal voice assessment.

Thyroid insufficiency

Following subtotal thyroidectomy this usually occurs within two years, but there is a small but progressive annual incidence over many years which is often insidious and difficult to recognise. With longer follow up it is clear that the majority of patients will eventually develop thyroid failure. This results from a change in the autoimmune response from stimulation to destruction of thyroid cells. There is, however, a definite relationship between the estimated weight of the thyroid remnant and the development of thyroid failure after subtotal thyroidectomy for Graves' disease. Thyroid insufficiency is rare after surgery for a toxic adenoma, because there is no autoimmune disease present.

Parathyroid insufficiency

This is due to removal of the parathyroid glands or infarction through damage to the parathyroid end artery; often, both factors occur together. Vascular injury is probably far more impor-

tant than inadvertent removal. The incidence of permanent hypoparathyroidism should be less than 1 per cent and most cases present dramatically 2–5 days after operation but, very rarely, the onset is delayed for 2–3 weeks or if a patient with marked hypocalcaemia is asymptomatic.

Thyrotoxic crisis (storm)

This is an acute exacerbation of hyperthyroidism. It occurs if a thyrotoxic patient has been inadequately prepared for thyroidectomy and is now extremely rare. Very rarely, a thyrotoxic patient presents in a crisis and this may follow an unrelated operation. Symptomatic and supportive treatment is for dehydration, hyperpyrexia and restlessness. This requires the administration of intravenous fluids, cooling the patient with ice packs, administration of oxygen, diuretics for cardiac failure, digoxin for uncontrolled atrial fibrillation, sedation and intravenous hydrocortisone. Specific treatment is by carbimazole 10–20 mg 6-hourly, Lugol's iodine 10 drops 8-hourly by mouth or sodium iodide 1 g i.v. Propranolol intravenously (1–2 mg) or orally (40 mg 6-hourly) will block β -adrenergic effects.

Wound infection

Cellulitis requiring prescription of antibiotics, often by the general practitioner, is more common than most surgeons appreciate. A significant subcutaneous or deep cervical abscess is exceptionally rare and should be drained.

Hypertrophic or keloid scar

This is more likely to form if the incision overlies the sternum and in dark-skinned individuals. Intradermal injections of corticosteroid should be given at once and repeated monthly if necessary. Scar revision rarely results in significant long-term improvement.

Stitch granuloma

This may occur with or without sinus formation and is seen after the use of non-absorbable, particularly silk, suture material. Absorbable ligatures and sutures must be used throughout thyroid surgery. Some surgeons use a subcuticular absorbable skin suture rather than the traditional skin clips or staples. Skin staples, if used, can be removed safely in less than 48 hours because the skin closure is supported by the platysma stitch.

Postoperative care

About 25 per cent of patients develop transient hypocalcaemia and oral calcium may be necessary (1 g three to four times daily). If associated symptoms are severe, and serum calcium less than 1.90 mmol/L, 10 mL intravenous calcium gluconate 10 per cent (10 mL equivalent to 8.9 mg or 2.3 mmol calcium) should be given and alfacalcidol (1–2 μ g oral daily) may be required to maintain normocalcaemia. To screen for parathyroid insufficiency, the serum calcium should be measured at the first review attendance 4–6 weeks after operation.

After subtotal resection, stability in terms of thyroid function takes time. It is important that biochemical (subclinical) thyroid failure should not be an indication for treatment during the first year, as the majority of patients with early subclinical failure, which is common, ultimately regain normality. Even when there are clinical features of failure, thyroxine should be withheld if possible during the first six months. Most patients who develop thyroid failure do so within the first two years, but there is a

continuing incidence thereafter. Recurrent thyrotoxicosis may occur at any time after operation. Follow up should therefore be for life.

Once a stable situation has been achieved, follow up after thyroid surgery should be carried out by an automated computerised system, which dramatically reduces the number of patient attendances at the thyroid clinic (Summary box 51.5).

NEOPLASMS OF THE THYROID

Thyroid neoplasms are classified in Table 51.7 and the relative incidence of malignancies in Table 51.8.

Benign tumours

Follicular adenomas present as clinically solitary nodules (Figure 51.35) and the distinction between a follicular carcinoma and an adenoma can only be made by histological examination; in the adenoma there is no invasion of the capsule or of pericap-

Figure 51.35 Isolated swelling in upper pole right thyroid lobe.

sular blood vessels. Treatment is, therefore, by wide excision, i.e. lobectomy. The remaining thyroid tissue is normal so that prolonged follow up is unnecessary. It is doubtful if there is such an entity as a papillary adenoma and all papillary tumours should be considered as malignant even if encapsulated.

Malignant tumours

The vast majority of primary malignancies are carcinomas derived from the follicular cells (Table 51.7). Dunhill classified them histologically as differentiated and undifferentiated: and the differentiated carcinomas are subdivided into follicular and papillary. Lymphoma and medullary cancers make up the remainder of primary malignancies. Metastases to the thyroid, most commonly from kidney and breast, are rare. Direct invasion by upper aerodigestive squamous cancer is a rare but lethal event. Lymph node and blood-borne metastases to bone and lung occur and may be the mode of presentation (Figure 51.36).

Aetiology of malignant thyroid tumours

The single most important aetiological factor in differentiated thyroid carcinoma, particularly papillary, is irradiation of the

Table 51.7 Classification of thyroid neoplasms.

Benign	Follicular adenoma		
Malignant	Primary	Follicular epithelium – differentiated	Follicular Papillary
		Follicular epithelium – undifferentiated	Anaplastic
		Parafollicular cells	Medullary
		Lymphoid cells	Lymphoma
	Secondary	Metastatic Local infiltration	

Table 51.8 Relative incidence of primary malignant tumour of the thyroid gland.

In 1943, Edwin Bennett Astwood from Boston first treated **thyrotoxicosis** successfully with thiourea.

Figure 51.37 Follicular neoplasm of thyroid presenting as an isolated swelling.

thyroid under five years of age. The incidence of childhood thyroid cancer in the Ukraine rose from 57 in the five years before the Chernobyl nuclear incident in 1986 to 577 in the subsequent ten years. In the town of Gomel, the incidence rose from <1 per million to 96 per million.

Short latency aggressive papillary cancer is associated with the *ret/PTC3* oncogene and later developing, possibly less aggressive, cancers with *ret/PTC1*. The incidence of follicular carcinoma is high in endemic goitrous areas, possibly due to TSH stimulation. Malignant lymphomas sometimes develop in autoimmune thyroiditis, and the lymphocytic infiltration in the autoimmune process may be an aetiological factor.

Clinical features of thyroid cancers

The annual incidence is about 3.7 per 100 000 of the population and the sex ratio is three females to one male. The overall mortality should be low because most patients are in a low-risk category but older patients have more aggressive disease with a worse prognosis. The most common presenting symptom is a thyroid swelling (Figures 51.35 and 51.37) and a five-year history is far from uncommon in differentiated growths. Enlarged cervical lymph nodes may be the presentation of papillary carcinoma. Recurrent laryngeal nerve paralysis is very suggestive of locally advanced disease.

Anaplastic growths are usually hard, irregular and infiltrating. A differentiated carcinoma may be suspiciously firm and irregular, but is often indistinguishable from a benign swelling. Small papillary tumours may be impalpable, even when lymphatic metastases are present. Pain, often referred to the ear, is frequent in infiltrating growths.

Figure 51.38 Magnetic resonance imaging scan of papillary cancer with multiple node metastases.

Diagnosis of thyroid neoplasms

Diagnosis is obvious on clinical examination in most cases of anaplastic carcinoma, although Riedel's thyroiditis (see later) is indistinguishable. The localised forms of granulomatous and lymphocytic thyroiditis may simulate carcinoma. It is not always easy to exclude a carcinoma in a multinodular goitre, and solitary nodules, particularly in the young male, are always suspect. Failure to take up radioiodine is characteristic of almost all thyroid carcinomas (only very rarely will differentiated carcinoma (primary or secondary) take up ^{123}I in the presence of normal thyroid tissue), but this also occurs in degenerating nodules and all forms of thyroiditis. TSH levels are often raised in carcinoma but this may be clouded by simultaneous elevation antithyroid antibodies. The key role of FNAC in preoperative diagnosis has already been discussed. There is a false-negative rate with all investigations, and lobectomy is appropriate when there is a strong clinical suspicion. Incisional biopsy may cause seeding of cells and local recurrence, and is not advised in a resectable carcinoma. In an anaplastic and obviously irremovable carcinoma, however, incisional or core needle biopsy is justified.

When a preoperative diagnosis is made, imaging with either ultrasound or MRI is required. CT, particularly with iodine containing contrast media, should be avoided. As well as additional information on the extent of the primary, this will give valuable information on nodal involvement (Figures 51.38 and 51.39) to permit preoperative planning for nodal dissection.

Figure 51.39 Composite ultrasound scan of papillary cancer of right thyroid lobe with extensive nodal metastases. N, enlarged nodes; C, carotid artery; R, primary carcinoma in right thyroid lobe; L, normal left thyroid lobe (courtesy Dr D McAteer, Aberdeen, UK).

Frozen section histology has a limited role in thyroid surgery. It cannot reliably differentiate encapsulated benign from malignant follicular neoplasms and is of more value in confirming whether nodes are involved with papillary cancer and thereby influencing the extent of nodal surgery.

Papillary carcinoma

Most papillary tumours contain a mixture of papillary and colloid-filled follicles and, in some, the follicular structure predominates. Nevertheless, if any papillary structure or characteristic cytology is present, the tumour will behave in a predictable fashion as a papillary carcinoma. Histologically the tumour shows papillary projections and characteristic pale, empty nuclei (Orphan Annie-eyed nuclei) (Figure 51.40). Papillary carcinomas are very seldom encapsulated.

Multiple foci may occur in the same lobe as the primary tumour or, less commonly, in both lobes. They may be due to lymphatic spread in the rich intrathyroidal lymph plexus, or to multicentric growth. Spread to the lymph nodes is common, but blood-borne metastases are unusual unless the tumour is extrathyroidal. The term extrathyroidal indicates that the primary tumour has infiltrated through the capsule of the thyroid gland although minimal invasion of the sternothyroid muscle is much less significant than infiltration into the oesophagus or trachea.

Microcarcinoma (occult carcinoma)

The reported prevalence of tiny foci of papillary carcinoma is related to the care with which the thyroid is examined

Figure 51.40 Histology of papillary thyroid carcinoma showing typical papillary projections and empty (Orphan Annie-eyed) nuclei (courtesy of Dr SWB Ewen, Aberdeen, UK).

histologically. In an autopsy study from Finland in which the thyroid was examined serially in 2-mm slices, an incidence of up to 36 per cent was reported. Clearly, the majority of such tumours never progress to become a clinically significant entity. A small percentage of cancers present with enlarged lymph nodes in the jugular chain or pulmonary metastases with no palpable abnormality of the thyroid. The primary tumour may be no more than a few millimetres in size and is often termed occult. Foci of papillary carcinoma may also be discovered in thyroid tissue resected for other reasons, for example Graves' disease. The term 'occult' was formally applied to all papillary carcinomas less than 1.5 cm in diameter but the preferred terminology now is microcarcinoma for cancers less than 1 cm. These have a uniformly excellent prognosis although those presenting with nodal or distant metastases justify more aggressive therapy.

Follicular carcinoma

These appear to be macroscopically encapsulated but, microscopically, there is invasion of the capsule and of the vascular spaces in the capsular region (Figure 51.41). Multiple foci are seldom seen and lymph node involvement is much less common than in papillary carcinoma. Blood-borne metastases are more common and the eventual mortality rate is twice that of papillary cancer (Figure 51.42).

Hürthle cell tumours are a variant of follicular neoplasm in which oxyphil (Hürthle, Askanazy) cells predominate histologically. Hurthle cell cancers are associated with a poorer prognosis and some hold that all Hurthle cell neoplasms are malignant.

Figure 51.41 Histology of follicular thyroid carcinoma showing vascular (red arrow) and capsular (black arrow) invasion (courtesy of Dr SWB Ewen, Aberdeen, UK).

Figure 51.42 Follicular carcinoma of thyroid with skull secondaries.

Prognosis in differentiated thyroid carcinoma

The prognosis in differentiated thyroid carcinoma compared to most cancers is excellent. Although influenced by histological type, prognosis is much more dependent on age at diagnosis, size of the tumour, metastatic disease and the presence of either extrathyroidal spread (in papillary cancer) or major capsular transgression (in follicular carcinoma). There are a multiplicity of scoring systems all of which identify the group of patients at high (40 per cent at 20 years) or low (1 per cent at 20 years) risk of death (Table 51.9). All patients should be TNM staged and this classification acknowledges the low risk of patients aged less than 45 years at presentation (Table 51.10). Approximately 80 per cent of patients are at a low risk of dying of thyroid cancer but suboptimal treatment, i.e. failure to eradicate all macroscopic disease at the first operation, may lead to increased recurrence and avoidable deaths many years after presentation. It is, however, important to avoid iatrogenic morbidity by overzealous treatment in those patients with a normal life expectancy.

Surgical treatment

Patients with large, locally aggressive or metastatic differentiated thyroid cancer (DTC) require total thyroidectomy, with excision of adjacent involved structures if necessary, and appropriate nodal surgery followed by radioiodine ablation with long-term TSH suppression. Such 'high risk' patients however are in the minority and there is continuing disagreement on the most appropriate operation for 'low risk' differentiated thyroid carcinoma, particularly with the increase in diagnosis of incidental microcarcinomas of less than 1 cm. Current guidelines advocate routine total thyroidectomy, often necessitating early

Table 51.10 Tumour–node–metastasis (TNM) staging of thyroid cancer.

reoperation and second lobectomy following a diagnostic first lobectomy with routine central compartment node dissection for all tumours greater than 1 cm. Total thyroidectomy facilitates the use of radioiodine for postoperative scanning to detect and subsequently ablate metastases results in lower thyroglobulin levels. An undetectable serum thyroglobulin is increasingly used as a proxy for cure. While this policy may reduce the rate of reoperation for recurrent disease it is unlikely to improve on existing 99 per cent survival in low risk patients and exposes patients to increased risk of RLN injury, hypoparathyroidism and later development of second cancers.

Local recurrence, in either the thyroid bed or contralateral lobe, should be exceptionally rare after total lobectomy, particularly in low risk cases. A randomised trial would have to recruit several thousand patients and take 50 years to resolve this debate. For the foreseeable future, many patients will be overtreated until a reliable method of identifying those who will benefit is established.

It is the author's current practice when a **preoperative diagnosis** of DTC has been made, usually on FNAC, to image the neck with ultrasound or MRI (Figures 51.36 and 51.37). The imaging will identify involved lymph node levels and permit

Karl Hürthle, 1866–1945, a German histopathologist who first drew attention to these cells.

Max Askanazy, 1865–1940, described these cells while working at the Pathological Anatomy Institute, Tübingen, Germany.

operative planning. Total thyroidectomy is recommended for tumours greater than 2 cm and those with nodal involvement or metastases and lobectomy for the remainder. Functional selective node dissection of involved node levels is performed as required. Lateral extension of the normal thyroidectomy incision generally gives adequate access to node levels 3–7. If access to level 2 is difficult an additional higher skin crease incision or alternatively a J-shaped utility incision may be made. Surgery should aim to remove all macroscopic disease (Figure 51.43).

There is a practical difference between a 'diagnostic' central compartment dissection in patients with no obvious nodal involvement and a 'therapeutic' clearance for macroscopic disease. A 'diagnostic' dissection can be limited to selective unilateral node dissection often with preservation of the thymus whereas a 'therapeutic' dissection requires clearance of all tissue to the level of the innominate vein. Very occasionally, it may be necessary to sacrifice the recurrent laryngeal nerve if it is completely encircled and, on even more rare occasions, extrathyroidal spread may require tracheal, oesophageal or laryngeal resection. Such procedures are not for the occasional surgeon. When the diagnosis of DTC is made **after diagnostic lobectomy** TSH suppression and review can be recommended with reoperation only for a clear indication. Indications for completion total thyroidectomy are the development of a new swelling or rising thyroglobulin. This is based on analysis of the outcome of thyroid lobectomy in the author's unit in both 'low' and 'high' risk patients since 1977.

Additional measures

Thyroxine

It is standard practice to prescribe thyroxine in a dose of 0.1–0.2 mg daily, to suppress endogenous TSH production, for all patients after operation for differentiated thyroid carcinoma on the basis that most tumours are TSH dependent. Suppression of the TSH level should be confirmed by measurement. Failure of suppression to a level of <0.1 mU/L may indicate an inadequate dose of thyroxine or, more usually, that the patient is non-compliant. There is a trend to manage patients with undetectable thyroglobulin after radical treatment with a TSH level in the normal range because of some concern over the impact of long-term TSH suppression.

Thyroid hormone replacement is obviously necessary after total thyroidectomy and in the majority of patients after near-total thyroidectomy, and is usually given in the form of thyroxine. Patients with potential or actual distant metastases, who may require repeated radioiodine administration for scanning and therapy, should be given tri-iodothyronine (60–80 µg per day) because it is much shorter acting and, on stopping it, increased TSH secretion and thyroid avidity for iodine recovers quickly so that radioiodine may be given after 7 days. The patient is thereby spared the 4 weeks needed to develop thyroid insufficiency after stopping thyroxine before radioiodine may be given. An alternative to thyroxine withdrawal is to administer recombinant synthetic TSH over a 48-hour period to maximise iodine uptake. This is an equally effective but more expensive regime.

Radioiodine

If metastases take up radioiodine, they may be detected by scanning and treated with large doses of radioiodine. For effective

Figure 51.43 (a) Completed dissection for papillary cancer including median sternotomy with clearance of nodes from levels II–VII bilaterally and extensive mediastinal nodes. scanning, all normal thyroid tissue must have been ablated either by surgery or preliminary radioiodine and the patient must be hypothyroid to improve uptake. Alternatively, synthetic recombinant TSH may be used to stimulate uptake. The indications for scanning after operations for differentiated carcinoma are also disputed, but radioiodine is indicated in patients with unresectable disease, local recurrence or metastatic disease, high-risk patients, and in those with a rising serum thyroglobulin level. A whole body scan can be carried out after empiric treatment with high-dose radioiodine 10 days later to allow decay of activity (Figure 51.44). Unfortunately, the more aggressive and de-differentiated the cancer the more likely it is not to take up radioiodine: those most in need of an effect are least likely to derive benefit.

If metastases have been treated, the serum thyroglobulin level and local protocols will determine when the scan should be repeated and further therapeutic doses of radioiodine given if necessary. Solitary distant metastases may be treated by external radiotherapy.

Thyroglobulin

The measurement of serum thyroglobulin is invaluable in the follow up and detection of metastatic disease in patients who have undergone surgery for differentiated thyroid cancer. It can be used after lobectomy, as after total thyroidectomy, provided that endogenous TSH production has been suppressed by T_4 . This measurement reduces the need for serial radioactive iodine scanning but, when a rise occurs, imaging with neck ultrasound is appropriate. Surgery or therapeutic radioiodine is then indicated with a subsequent whole body scan once activity has decayed (Figure 51.45). This will confirm and locate metastatic disease which is iodine avid. The presence of circulating antithyroglobulin antibodies interferes with and invalidates thyroglobulin as a serum marker for recurrence, and occasionally, careful clinical palpation of the neck will be the first indication of local recurrence.

Figure 51.45 Whole body scan post-radioactive iodine ablation showing activity in recurrent lymph nodes in left level V.

Undifferentiated (anaplastic) carcinoma

This occurs mainly in elderly women and is much less often diagnosed now than in the past when many thyroid lymphomas were mistakenly classified histologically as anaplastic carcinomas. Local infiltration is an early feature of these tumours with spread by lymphatics and by the bloodstream. They are extremely lethal tumours and survival is calculated in months. Complete resection is justified if the disease appears confined to the thyroid and possibly the strap muscles and is only possible in a minority of patients. Even then the survival rarely exceeds six months and the median is around three months for the whole group. Some of these aggressive lesions present in an advanced stage with tracheal obstruction and they require urgent tracheal decompression. The trachea may be decompressed and tissue obtained for histology by isthmusectomy. Tracheostomy is best avoided. Radiotherapy should be given in all cases and may provide a worthwhile period of palliation, but there is little evidence to support the use of chemotherapy outwith clinical trials.

Medullary carcinoma

These are tumours of the parafollicular (C cells) derived from the neural crest and not from the cells of the thyroid follicle as are other primary thyroid carcinomas. The cells are not unlike those of a carcinoid tumour and there is a characteristic amyloid stroma (Figure 51.46). High levels of serum calcitonin and carcinoembryonic antigen are produced by many medullary tumours. Calcitonin levels fall after resection and rise again with recurrence making it a valuable tumour marker in the follow up of patients with this disease. Diarrhoea is a feature in 30 per cent of cases and this may be due to 5-hydroxytryptamine or prostaglandins produced by the tumour cells.

Some tumours are familial and account for 10–20 per cent of all cases. Medullary carcinoma may occur in combination with

Figure 51.46 Histology of medullary carcinoma showing characteristic 'cell balls' and amyloid (courtesy of Dr SWB Ewen, Aberdeen, UK).

adrenal pheochromocytoma and hyperparathyroidism (usually due to hyperplasia) in the syndrome known as multiple endocrine neoplasia (MEN) type 2A (MEN-2A). The familial form of the disease frequently affects children and young adults, whereas the sporadic cases occur at any age with no sex predominance. When the familial form is associated with prominent mucosal neuromas involving the lips, tongue and inner aspect of the eyelids, with a Marfanoid habitus, the syndrome is referred to as MEN type 2B (see Chapter 52).

Involvement of lymph nodes occurs in 50–60 per cent of cases of medullary carcinoma and blood-borne metastases are common. As would be expected, tumours are not TSH dependent and do not take up radioactive iodine. The prognosis is variable and depends on the stage at diagnosis. Any nodal involvement virtually eliminates the prospect of cure and, unfortunately, even small tumours confined to the thyroid gland may have spread by the time of diagnosis, particularly in familial cancers. In common with many endocrine tumours the progression of disease may be very slow with a characteristically indolent course and long survival, even in the absence of cure.

Treatment

Treatment is by total thyroidectomy and either prophylactic or therapeutic resection of central and bilateral cervical lymph nodes.

Familial cases are now detected by genetic screening for the *RET* mutations, which identifies individuals who will develop medullary cancer later in life (Figure 51.47). The genetic tests are supplemented by estimating serum calcitonin levels in the basal state and after stimulation by either calcium or pentagastrin. A rise in calcitonin levels under these circumstances should lead to thyroidectomy, but even then the disease may be beyond the preinvasive C-cell hyperplasia stage (Figure 51.48). Prophylactic surgery is recommended for infants with the genetic trait. Detailed preoperative genetic and biochemical analyses permit a tailored approach to nodal surgery and may avoid unnecessarily radical surgery. A recent refinement as a result of preoperative genetic differentiation between sporadic and familial cancers suggests that lobectomy might be adequate treatment for sporadic cases.

In all cases, before embarking upon thyroid surgery,

Figure 51.47 Hyperplasia of parafollicular C cells in a child from a family with medullary cancer (courtesy of Dr SWB Ewen, Aberdeen, UK).

pheochromocytoma must be excluded by measurement of urinary catecholamine levels.

Malignant lymphoma

In the past, many malignant lymphomas were diagnosed as small round-cell anaplastic carcinomas. Response to irradiation is dramatic (Figure 51.49) and radical surgery is unnecessary once the diagnosis is established by biopsy. Although the diagnosis may be made or suspected on FNAC, sufficient material is seldom available for immunocytochemical classification and core needle or open biopsy is usually necessary. In patients with tracheal compression, isthmusectomy is the most appropriate form of biopsy although the response to therapy is so rapid that this should rarely be necessary unless there has been difficulty in making a histological diagnosis. The prognosis is good if there is no involvement of cervical lymph nodes. Rarely, the tumour is part of widespread malignant lymphoma disease, and the prognosis in these cases is worse. Most lymphomas occur against a background of lymphocytic thyroiditis (Summary box 51.6).

THYROIDITIS

Chronic lymphocytic (autoimmune) thyroiditis

This common condition is usually associated with raised titres of thyroid antibodies. Not infrequently there is a family history of other autoimmune disease. It commonly presents as a goitre, which may be diffuse or nodular with a characteristic 'bosselated' feel or with established or subclinical thyroid failure. The diagnosis often follows investigation of a discrete swelling. Features of chronic lymphocytic (focal) thyroiditis are commonly present on histological examination in association with other thyroid

disease, notably toxic goitre. Primary myxoedema without detectable thyroid enlargement represents the end stage of the pathological process.

Clinical features

The onset, thyroid status and the type of goitre vary profoundly from case to case. The onset may be insidious and asymptomatic, or so sudden and painful that it resembles the acute form of granulomatous thyroiditis. Mild hyperthyroidism may be present initially, but hypothyroidism is inevitable and may develop rapidly or extremely slowly. The goitre is usually lobulated, and may be diffuse or localised to one lobe. It may be large or small, and soft, rubbery or firm in consistency, depending upon the cellularity and the degree of fibrosis. The disease is most common in women at the menopause, but may occur at any age. Papillary carcinoma and malignant lymphoma are occasionally associated with autoimmune thyroiditis (Figure 51.50).

Diagnosis

Biochemical tests of thyroid function vary with the thyroid status and are of diagnostic value only if hypothyroidism is present. Significantly, raised serum levels of one or more thyroid antibodies are present in over 85 per cent of cases. Nevertheless, differential diagnosis from nodular goitre, carcinoma and malignant lymphoma of the thyroid is not always easy. FNAC is the most appropriate investigation although abundant lymphocytes may make the cytological distinction between autoimmune thyroiditis and lymphoma difficult. When there is doubt about neoplastic disease, which may coexist with thyroiditis, diagnostic lobectomy may be necessary.

Treatment

Full replacement dosage of thyroxine should be given for hypothyroidism and if the goitre is large or symptomatic, because some (under TSH stimulation) may subside with hormone therapy. More minor manifestations of the condition such as a small goitre with raised antibody titres, or histological evidence of thyroiditis in association with other thyroid disease, do not justify thyroxine replacement if thyroid function is biochemically normal; however, long-term surveillance is necessary because of

Figure 51.50 Autoimmune thyroiditis (Hashimoto's disease; struma lymphomatosa). Intense lymphocytic-plasma cell infiltration, acinar destruction and fibrosis. Compare with the normal histology shown in Figure 51.2.

the risk of late thyroid failure. Occasionally, the goitre increases despite hormone treatment and, in these circumstances, there may be a favourable response to steroid therapy. Thyroidectomy may be necessary if the goitre is large and causes discomfort. Increase in size of a long-standing lymphocytic goitre should be assessed urgently because of the possibility of the development of malignant lymphoma.

Granulomatous thyroiditis (subacute thyroiditis, de Quervain's thyroiditis)

This may follow a viral infection. In a typical subacute presentation, there is pain in the neck, fever, malaise and a firm, irregular enlargement of one or both thyroid lobes. There are raised inflammatory markers, absent thyroid antibodies, the serum T_4 is high normal or slightly raised, and the ^{123}I uptake of the gland is low. The condition is self-limiting and, in a few months, the goitre subsides and there may be a period of months of hypothyroidism before eventual recovery. In 10 per cent of cases the onset is acute, the goitre very painful and tender and there may be symptoms of hyperthyroidism. One-third of cases are asymptomatic but for the presence of the goitre. If diagnosis is in doubt, it may be confirmed by FNAC, radioactive iodine uptake and by a rapid symptomatic response to prednisone. The specific treatment for the acute case with severe pain is to give prednisone 10–20 mg daily for 7 days and the dose is then gradually reduced over the next month. If thyroid failure is prominent, treatment with thyroxine may be required until function recovers.

Riedel's thyroiditis

This is very rare, accounting for 0.5 per cent of goitres. Thyroid tissue is replaced by cellular fibrous tissue, which infiltrates through the capsule into muscles and adjacent structures, including parathyroids, recurrent nerves and carotid sheath. It may occur in association with retroperitoneal and mediastinal fibrosis and is most probably a collagen disease. The goitre may be unilateral or bilateral and is very hard and fixed. The differential diagnosis from anaplastic carcinoma can be made with certainty only by biopsy, when a wedge of the isthmus should also be removed to free the trachea. If unilateral, the other lobe is usually involved later and subsequent hypothyroidism is common. Treatment is with high-dose steroid, tamoxifen and thyroxine replacement. Reduction in size of the goitre and long-term improvement in symptoms are to be expected if treatment is commenced early (Summary box 51.7).

PARATHYROID HYPERPARATHYROIDISM

Primary hyperparathyroidism

Primary hyperparathyroidism is commonly a sporadic rather than familial condition associated with hypercalcaemia and

inappropriately raised serum PTH levels due to enlargement of one or more glands and hypersecretion of PTH. The normal response to hypercalcaemia is PTH suppression.

Epidemiology

The prevalence of sporadic primary hyperparathyroidism increases with age and affects women more than men. Approximately 1 per cent of adults are hypercalcaemic on biochemical screening.

Familial hyperparathyroidism occurs as part of the following genetically determined conditions:

- MEN1 (multiple endocrine neoplasia type 1: Werner's syndrome);
- MEN2A (Sipple syndrome), rarely in MEN2B;
- Familial hyperparathyroidism.

Pathology

The majority (85 per cent) of patients with sporadic primary hyperparathyroidism have a single adenoma, approximately 13 per cent have hyperplasia affecting all four glands and about 1 per cent will have more than one adenoma or a carcinoma. In familial disease, multiple gland enlargement is usual.

There is a weak correlation between the size of an adenoma and the level of PTH (Figure 51.51). The histological differentiation between adenoma and hyperplasia can be difficult and the macroscopic findings are an important determinant in making the diagnosis. A single enlarged gland with three small normal glands is characteristic of a single adenoma regardless of the histology which may show considerable overlap between a hyperplastic and adenomatous gland. Multiple adenomas occur more frequently in older patients.

Parathyroid hyperplasia by definition affects all four glands (Figure 51.52).

Parathyroid carcinomas are large tumours and typically much more adherent or even frankly invasive than large adenomas. Histology demonstrates a florid desmoplastic reaction with dense fibrosis and capsular and vascular invasion.

Parathyroid cysts may be secondary to degeneration in nodules or adenomas, developmental and, while some present as a palpable neck swelling, small cysts are most often noted as

Figure 51.51 Parathyroid adenoma. Operative photograph showing normal left inferior parathyroid (IPG) and large left superior parathyroid adenoma (SPG).

Figure 51.52 Parathyroid hyperplasia. (a) Mobilised right thyroid lobe showing enlarged superior and inferior parathyroid glands. Note how the superior gland has migrated posterior and inferior to the inferior thyroid artery. (b) Total parathyroidectomy specimens.

incidental findings during neck exploration. If aspirated preoperatively the diagnosis should be suspected from the watery clear fluid aspirated. The diagnosis is confirmed by a high PTH level.

Clinical presentation

The classic quartet of 'stones, bones, abdominal groans and psychic moans' is rarely observed in developed countries when the diagnosis is usually detected on serum calcium estimation well before the full picture of severe bone disease (von Recklinghausen's disease), renal calculi and calcinosis, pancreatitis and psychiatric disorder. Incidentally detected hypercalcaemia is rarely truly 'asymptomatic' and most patients experience an improved sense of well-being after surgery. Careful enquiry into family history is always appropriate and may reveal an index case for familial disease including familial primary HPT, MEN syndromes and familial hypocalciuric hypercalcaemia.

Diagnosis

Although ionised calcium is the physiologically active circulating element, total serum calcium is a satisfactory measure. The effect of binding to serum proteins must be corrected by

upward or downward correction to a serum albumin level of 40 g/L. Inappropriate, i.e. elevated or normal PTH levels in the presence of high serum calcium is diagnostic of primary HPT. Hypophosphataemia and elevated urine calcium excretion are confirmatory.

Other causes of hypercalcaemia must be considered and excluded (Table 51.11). Advanced malignancy is the most common cause of hypercalcaemia in hospitalised patients, due to parathyroid hormone-related peptide (PTHrP) or bone metastases. The PTH level is suppressed.

Familial hypocalciuric hypercalcaemia is an autosomal dominant disorder characterised by mild elevation of calcium and PTH levels secondary to a missense mutation in the cell membrane calcium receptor. The low urinary excretion of calcium will discriminate this from HPT. Parathyroidectomy is not required. However, neonatal hyperparathyroidism is rare but is associated with severe hypercalcaemia in homozygous patients and urgent near-total parathyroidectomy is required.

Table 51.11 Causes of hypercalcaemia.

Endocrine	Primary hyperparathyroidism Thyrotoxicosis Pheochromocytoma Adrenal crisis
Renal failure	Secondary hyperparathyroidism Tertiary hyperparathyroidism
Malignant disease	Skeletal secondaries Myeloma
Nutritional	Milk alkali syndrome Excess vitamin D intake
Granulomatous disease	Tuberculosis Sarcoidosis
Immobilisation	
Inherited disorders	Hypercalciuric hypercalcaemia

Treatment of primary hyperparathyroidism

At present surgery is the only curative option and should be offered to all patients with significant hypercalcaemia provided they are otherwise fit for the procedure. There are a number of medical strategies and therapies, particularly in mild hyperparathyroidism, which include simple expectant treatment until the calcium level or symptoms reach a level at which surgery becomes more attractive, low calcium diet, withdrawal of drugs (diuretics and lithium) which aggravate hypercalcaemia and, more recently, calcium reducing agents such as bisphosphonates and the calcium receptor agonist cinacalcet.

Occasionally, patients present with a parathyroid crisis and severe hypercalcaemia (serum calcium greater than 3.5 mmol/L). This results in confusion, nausea, abdominal pain, cardiac arrhythmias and hypotension with acute renal failure. Intravenous saline and bisphosphonate therapy (pamidronate) are required to correct the dehydration and hypercalcaemia. This is best done in a high-dependency unit or even intensive therapy unit setting to monitor the major physiological fluxes which result.

Indications for operation

Conventional indications for operation are shown in Table 51.12, but traditionally, endocrine surgeons have had a lower threshold for recommending operation than physicians. However, the widespread adoption of minimal access techniques for parathyroidectomy has changed many physicians' attitudes because of the perceived reduction in operative morbidity. There remains a cohort of patients with mild primary HPT and those with significant comorbidity where the decision for operation remains a matter of clinical judgement.

Table 51.12 Indications for parathyroidectomy in primary hyperparathyroidism.

Urinary tract calculi
Reduced bone density
High serum calcium ^a
‡ All in younger age group <50 years
Deteriorating renal function
Symptomatic hypercalcaemia

^aVariably set between 2.85 and 3.00 mmol/L.

Preoperative localisation

There has been a paradigm shift in the use of preoperative imaging in primary hyperparathyroidism. Until a few years ago the maxim that the 'only localisation test necessary was to locate a good endocrine surgeon' (Doppman) was apposite when opinion favoured a conventional bilateral neck exploration. Skilled surgeons can achieve cure rates of the order of 98 per cent, with failure due to an ectopic adenoma not accessible through a cervical incision or, occasionally, failure to recognise multiple gland disease. While there should be minimal morbidity associated with a bilateral neck exploration, an image-guided targeted approach reduces this even further and has become routine in most major centres. Concerns that subtle abnormalities will be missed if all glands are not routinely visualised remain but have not translated into a significant clinical issue to date. There remains a cohort of patients in whom preoperative imaging

does not localise an adenoma and the experience of the surgeon remains paramount in achieving a high cure rate.

High frequency neck ultrasound is non-invasive and should identify 75 per cent of enlarged glands. It gives better resolution but reduced penetration and cannot visualise the mediastinum (Figure 51.53). Nodular thyroid disease is a confounding factor.

Technetium-99m (99mTc)-labelled sestamibi (MIBI) isotope scans (Figure 51.54) also identify 75 per cent of abnormal parathyroid glands. The area scanned must include the mediastinum to detect ectopic glands. Single-photon emission computed tomography (SPECT) (Figure 51.55) gives a three-dimensional image which may influence the surgical approach. Concordance between ultrasound and sestamibi scan permits a targeted approach with confidence. However, the size of the adenoma is important and imaging and concordance decline with glands weighing less than 500 mg.

CT, PET and MRI imaging are not indicated prior to first-time neck exploration.

Figure 51.54 Technetium-sestamibi scans 15 minutes and 3 hours after injection showing retention of isotope in a left inferior parathyroid adenoma.

Figure 51.53 Ultrasound scan of parathyroid adenoma at upper pole right thyroid lobe. C, carotid artery; A, parathyroid adenoma; T, right thyroid lobe.

Figure 51.55 MIBI scan with single photon emission computed tomography showing hot spot in anterior mediastinum (arrow) (courtesy of Mr B Harrison, Sheffield, UK).

John L Doppman, contemporary, radiologist, Bethesda, MA, USA.
The noun *isotope* is derived from the Greek isos = equal and tops = place, meaning having an equal place on the periodic table.

Consent for surgery

Preoperative discussion must include the possibilities of:

- persistent hyperparathyroidism (5 per cent);
- recurrent laryngeal nerve injury (1 per cent);
- postoperative haemorrhage (1 per cent);
- permanent hypoparathyroidism;
- recurrent hyperparathyroidism.

Operation for primary hyperparathyroidism

There are a number of surgical options available, of which a targeted small incision approach and bilateral exploration using a conventional 'thyroidectomy' incision are the most frequently performed. Video-assisted (in which a video endoscope is used to reduce the size of incision and permit bilateral exploration) and totally endoscopic techniques with multiple punctures have not achieved much popularity. Methylene blue infusion to assist in gland identification has largely been abandoned. A gamma probe can be used to guide exploration following preoperative injection of technetium-labelled sestamibi. The short serum half-life of PTH means that intraoperative measurement can be used to confirm that the source of excess PTH production has been excised. This is a more physiological approach than surgical opinion supported by frozen section and is routine in many centres but is not infallible or inexpensive. Serum levels of PTH are measured pre-incision, pre-removal, 5 minutes after removal and 10 minutes after removal. The assay takes 30 minutes and if the percentage drop is not >50 per cent then further exploration is indicated.

Operative strategy and technique of parathyroidectomy

Targeted approach

General or local anaesthesia may be used. A head light and magnifying loupes or alternatively a 5-mm video laparoscope are useful. Confident preoperative localisation permits a 2–3 cm incision located over the site of the adenoma (Figure 51.56). This may be placed to permit extension to a formal bilateral exploration incision if the imaging is suboptimal. The subplatysmal plane is incised and either a midline or lateral approach to the strap muscles permits development of the plane between

Figure 51.56 Targeted parathyroid surgery; a 2-cm incision over left inferior parathyroid adenoma.

the thyroid capsule and carotid artery and jugular veins. The adenoma is easily identified in the anticipated site when imaging is concordant. It is carefully mobilised staying close to but avoiding rupture of the capsule. Identification of the recurrent laryngeal nerve is not routine and only bipolar diathermy should be used. Failure to immediately identify the gland may require an extended exploration which can be accomplished through a unilateral limited incision. Conversion to a formal neck incision and bilateral exploration should rarely be required if preoperative assessment has been rigorous.

Conventional approach

The patient is positioned in reverse Trendelenburg, with a silicone gel pad transversely under the shoulders to extend the neck with the head supported in a padded ring.

A transverse collar incision is made, the subplatysmal plane developed superiorly and inferiorly and the deep cervical fascia incised in the midline between the strap muscles. The thyroid lobes are mobilised with division of the middle thyroid vein when present. It is not normally necessary to divide the superior thyroid vessels unless the exploration proves difficult. Medial rotation of the thyroid lobe exposes the inferior thyroid artery and recurrent laryngeal nerve (Figures 51.5 and 51.52a). The glands are identified in a systematic manner commencing with the common sites and working sequentially through to the rare locations.

Superior gland:

- 1 in fat pad on surface of thyroid lobe above the inferior thyroid artery at level of cricothyroid articulation then
- 2 inferiorly behind the inferior thyroid artery and oesophagus then
- 3 divide superior thyroid vessels and rotate upper pole anteriorly.

Inferior gland:

- 1 along the thyrothymic axis then
- 2 on or under the capsule of the lower pole of the thyroid then
- 3 incise the fascia of the upper horn of thymus then
- 4 extend this down into the accessible mediastinal thymus then
- 5 within the carotid sheath (usually suggested by a tongue of ectopic thymus) then
- 6 transcervical thymectomy achieved by gentle upper retraction on the thymic lobe then
- 7 within the thyroid lobe which may require thyroid lobectomy.

All abnormal glands are excised and, in the event of sporadic four-gland disease, subtotal parathyroidectomy is carried out, preserving approximately 50 mg of one gland. This must be marked with a non-absorbable suture to facilitate any possible future re-exploration.

In patients with four-gland disease, transcervical thymectomy is recommended to reduce the risk of persistent or recurrent hyperparathyroidism. In patients with MEN-1, total parathyroidectomy reduces the risk of recurrence.

Preoperative imaging will identify the 1 per cent of patients with a mediastinal adenoma and allow a single curative operation (Figure 51.57a and b).

Figure 51.57 Mediastinal parathyroid adenoma. (a) Preoperative sestamibi scan with mediastinal adenoma (arrowed). (b) Operative photograph of median sternotomy showing a 4-cm parathyroid adenoma (courtesy Mr K Buchan, Aberdeen, UK).

Secondary hyperparathyroidism

Chronic renal failure results in secondary hyperparathyroidism. The kidney cannot convert vitamin D into the physiologically active 1,25-cholecalciferol. Reduced intestinal absorption of calcium resulting in a low serum calcium and elevated phosphate due to renal failure to excrete phosphate increases secretion of parathyroid hormone. Prolonged stimulation results in parathyroid hyperplasia. Initially this is reversible following renal transplantation but when autonomous hyperfunction progresses after transplantation this is termed tertiary hyperparathyroidism.

Secondary hyperparathyroidism also occurs in vitamin D-deficient rickets, malabsorption and pseudohypoparathyroidism.

Clinical and biochemical features

These include bone pain, pruritus, muscle weakness, renal osteodystrophy and soft-tissue calcification (Figure 51.58a and b). Calciphylaxis (calcific uremic arteriolopathy) is the end stage of

Figure 51.58 Secondary hyperparathyroidism. (a) Radiograph of ectopic calcification. (b) Computed tomography scan showing ectopic calcification in chest wall.

this condition with arteriolar occlusion resulting in cutaneous ulceration and gangrene. The systemic effects of these changes results in a high mortality and urgent parathyroidectomy may be required if the PTH is excessively high.

Treatment

Medical treatment of secondary hyperparathyroidism includes dietary phosphate restriction, calcium and vitamin D supplementation. Cinacalcet is not recommended except in patients unfit for surgery. Surgery is indicated when there is an excessive rise in the calcium/phosphate product and serum PTH. Patients are prepared with high-dose vitamin D (calcitriol) to reduce the severity of the profound hypocalcaemia which would otherwise follow parathyroidectomy. Preoperative dialysis is obligatory.

Operative strategy

Multiple-gland disease is usual although occasionally hyperparathyroidism secondary to single-gland disease is the cause rather than the consequence of renal failure. Options for management include total parathyroidectomy (Figure 51.52), total parathyroidectomy with autotransplantation of 50 mg parathyroid tissue into the brachioradialis or subtotal parathyroidectomy. The

Figure 51.59 Technetium-sestamibi scan at 3 hours showing a left superior parathyroid carcinoma.

latter is preferred if renal transplantation is likely. Transcervical thymectomy is indicated.

Even after subtotal parathyroidectomy or autotransplantation postoperative hypocalcaemia is inevitable. Preoperative preparation and oral calcitriol and calcium are mandatory. Intravenous calcium and magnesium are often required.

Parathyroid carcinoma

Cancer of the parathyroid is rare accounting for 1 per cent of cases of hyperparathyroidism. Typical features are very high calcium and PTH levels often with a palpable neck swelling or occasionally lymphadenopathy. Scanning may support the diagnosis (Figure 51.59). The diagnosis is rarely known at the time of exploration but, if suspected, operation should include excision of the tumour mass with *en bloc* thyroid lobectomy and node dissection when indicated. The diagnosis is difficult to make histologically and may only become apparent when recurrent disease presents with hypercalcaemia, increased serum PTH and evidence of local recurrence. Adjuvant or palliative radiotherapy may be indicated and overall survival as in most endocrine cancers is reasonable with 85 per cent five-year survival.

Persistent hyperparathyroidism

The first operation is the best opportunity to cure hyperparathyroidism surgically and when competently performed should be successful in more than 95 per cent of procedures. If hypercalcaemia persists after a first neck exploration the diagnosis, preoperative investigations, operative findings and pathology must be reviewed carefully. Referral to a specialist centre is prudent. If reoperation is appropriate, further investigation is required to localise the abnormal parathyroid tissue, usually a missed adenoma. This may be readily apparent but can require a combination of ultrasound, sestamibi, CT, MRI, PET, selective angiography (Figure 51.60) and venous sampling for PTH. The latter may be difficult to interpret if normal venous drainage has been disrupted by previous operations.

When the site of an ectopic or missed adenoma is accurately identified, a second operation can be straightforward when performed through intact tissue planes. Re-exploration through previously explored tissues is more difficult and increases the

Figure 51.60 Selective arteriogram of internal mammary artery showing parathyroid tumour blush in a patient who had undergone three previous neck explorations for HPT (courtesy of Mr B Harrison, Sheffield, UK).

risks to the recurrent laryngeal nerves and of postoperative hypocalcaemia.

Recurrent hyperparathyroidism

Recurrent hyperparathyroidism is diagnosed when hypercalcaemia recurs more than 12 months after an initially curative operation. This may occur due to:

- missed pathology at the first operation;
- (rarely) development of a second adenoma;
- hyperplasia in autotransplanted tissue;
- parathyromatosis (disseminated nodules of parathyroid tissue within the soft tissues of the neck and superior mediastinum caused by rupture of abnormal parathyroid tissue at initial surgery).

Reoperative parathyroid surgery is associated with an increased risk of recurrent laryngeal nerve injury and postoperative hypocalcaemia.

HYPOPARATHYROIDISM

While there are rare congenital (DiGeorge) and medical (autoimmune polyglandular and Wilson) syndromes causing hypoparathyroidism, for practical purposes postoperative

hypoparathyroidism is the dominant management issue in surgical practice. This results from removal, trauma or devascularisation of the parathyroid glands which may be deliberate but is more often inadvertent.

Symptoms and signs

The symptoms and signs of acute hypoparathyroidism are related to the level of serum calcium and range through mild circumoral and digital numbness and paraesthesia, to tetanic symptoms with carpopedal or laryngeal spasms, cardiac arrhythmia and fits. Chronic hypoparathyroidism can lead to abnormal bone demineralisation, cataracts, calcification in basal ganglia and consequent extrapyramidal disorders.

Percussion of the facial nerve just below the zygoma causes contraction of the ipsilateral facial muscles (Chvostek's sign). Carpopedal spasm can be induced by occlusion of the arm with a blood pressure cuff for 3 minutes (Trousseau's sign). Electrocardiogram changes include prolonged QT intervals and QRS complex changes.

Treatment

Acute symptomatic hypocalcaemia is a medical emergency and requires urgent correction by intravenous injection of calcium. Magnesium supplements may also be required. Oral calcium supplements (1 g three or four times daily) supplemented by 1–3 µg of 1-alpha-vitamin D if necessary should be given with a view to gradual withdrawal over the next 3–12 months. Lesser degrees of asymptomatic hypocalcaemia 1.90–2.10 mmol/L can be treated with oral calcium supplements of 3–4 g calcium per day in divided doses (Summary box 51.8).

Summary box 51.8

Management of postoperative hypocalcaemia

- Check serum calcium within 24 hours of total thyroidectomy or earlier if symptomatic
- Medical emergency if the level is <1.90 mmol/L: correct with 10 mL of 10 per cent calcium gluconate intravenously; 10 mL of 10 per cent magnesium sulphate intravenously may also be required
- Give 1 g of oral calcium three or four times daily
- Give 1–3 µg daily of oral 1-alpha-vitamin D if necessary

CHAPTER
52The adrenal glands
and other abdominal
endocrine disorders

LEARNING OBJECTIVES

To understand:

- The anatomy and function of the adrenal and other abdominal endocrine glands
- The diagnosis and management of these endocrine disorders
- The role of surgery in the management of these endocrine disorders

ADRENAL GLANDS**Anatomy**

The weight of a normal adrenal gland is approximately 4 g. There are two distinct components to the gland: the inner adrenal medulla and the outer adrenal cortex (Figure 52.1). The adrenal glands are situated near the upper poles of the kidneys, in the retroperitoneum, within Gerota's capsule. The right adrenal gland is located between the right liver lobe and the diaphragm, close to and partly behind the inferior vena cava. The left adrenal gland lies close to the upper pole of the left kidney and the renal pedicle. It is covered by the pancreatic tail and the spleen (Figure 52.2). The adrenal glands are well supplied by blood vessels. The arterial blood supply branches from the aorta and the diaphragmatic and renal arteries and varies considerably. A large adrenal vein drains on the right side into the vena cava and on the left side into the renal vein.

Embryology

The two functional parts, the cortex and the medulla, arise from different blastodermic layers: mesodermal cells form the adrenal cortex and neuroectodermal cells migrate to the cortex from the neural crest during embryogenesis and form the adrenal medulla.

Figure 52.1 Cross-section of a normal adrenal gland. The inner, very thin layer between the two dark lines (zona reticularis) is the adrenal medulla.

Figure 52.2 Position of the adrenal glands (hatched) in the retroperitoneum.

Histology

The adrenal cortex is arranged in a zonal configuration. The outer zona glomerulosa contains small, compact cells. The central zona fasciculata can be identified by larger, lipid-rich cells, which are arranged in radial columns. Compact and pigmented cells characterise the inner zona reticularis. The adrenal medulla consists of a thin layer of large chromaffin cells, which synthesise, store and secrete catecholamine.

Function of the adrenal glands

The adrenal glands play a pivotal role in the response to stress. Catecholamines are secreted by the adrenal medulla and corticosteroids, aldosterone and cortisol are synthesised in the adrenal cortex. Cells of the adrenal medulla synthesise mainly adrenaline (epinephrine) but also noradrenaline (norepinephrine) and dopamine. These catecholamines act as hormones as they are secreted directly into the circulation. Their effects, which are mediated through α and β receptors on target organs, include the cardiovascular system, resulting in an increase in blood pressure and heart rate; vasoconstriction of vessels in the splanchnic system and vasodilatation of vessels in the muscles; bronchodilatation; and increased glycogenolysis in liver and muscles: all necessary for the flight/fight response. Cells of the zona glomerulosa produce aldosterone, which regulates sodium–potassium homeostasis. The target organs of aldosterone are the kidneys, the sweat and salivary glands and the intestinal mucosa. Aldosterone promotes sodium retention and potassium excretion. The most important regulators of aldosterone secretion are the renin–angiotensin system and the serum potassium concentration. Renin produced by the juxtaglomerular cells in the kidneys acts on its substrate angiotensinogen to generate angiotensin I. Angiotensin I is converted by angiotensin-converting enzyme (ACE) to the octapeptide angiotensin II, which is modified to angiotensin III. Both stimulate the secretion of aldosterone from the adrenal cortex. A decrease in renal blood flow (haemorrhage, dehydration, salt depletion, orthostasis, renal artery stenosis) or hyponatraemia increases renin secretion and leads to sodium retention, potassium excretion and an increase of plasma volume.

Cells of the zona fasciculata and zona reticularis synthesise cortisol and the adrenal androgens dehydroepiandrosterone (DHEA) and its sulphate (dehydroepiandrosterone sulphate (DHEAS)). DHEA and DHEAS are precursors of androgens and are converted in peripheral tissues such as fat. Cortisol secretion is regulated by adrenocorticotrophic hormone (ACTH), which is produced by the anterior pituitary gland. The hypothalamus controls ACTH secretion by secreting corticotropin-releasing hormone (CRH). The serum cortisol level inhibits the release of CRH and ACTH via a closed-loop system (negative feedback loop).

Cortisol has numerous metabolic and immunological effects. It increases gluconeogenesis and lipolysis, decreases peripheral glucose utilisation, immunological response and muscular mass. It affects fat distribution, wound healing and bone mineralisation; and alters mood (euphoria or, rarely, depression) and cortical alertness.

DISORDERS OF THE ADRENAL CORTEX

Incidentaloma

Definition

Incidentaloma is an adrenal mass, detected incidentally by imaging studies conducted for other reasons, not known previously to have been present or causing symptoms.

Incidence

The prevalence of adrenal masses in autopsy studies ranges from 1.4 to 8.7 per cent and increases with age. Incidentalomas may

be detected on imaging studies in 1 per cent of patients. More than 75 per cent are non-functioning adenomas but Cushing's adenomas, pheochromocytomas, metastases, adrenocortical carcinomas and Conn's tumours can all be found this way (Table 52.1).

Table 52.1 Prevalence of non-functioning and functioning tumours in patients with incidentalomas.

Tumour	Prevalence (%)
Non-functioning adenoma	78
Cushing's adenoma	7
Adrenocortical carcinoma	4
Pheochromocytoma	4
Myelolipoma	2
Cyst	2
Metastases	2
Conn's adenoma	1

Diagnosis

When an incidentaloma is identified, a complete history and clinical examination are required. Occasionally, a previously occult endocrine disturbance will come to light. A biochemical work-up for hormone excess is needed and sometimes additional imaging studies are also required. The main goal is to exclude a functioning or malignant adrenal tumour.

Hormonal evaluation includes:

- morning and midnight plasma cortisol measurements;
- a 1-mg overnight dexamethasone suppression test;
- 24-hour urinary cortisol excretion;
- 12 or 24-hour urinary excretion of metanephrines or plasma-free metanephrines;
- serum potassium, plasma aldosterone and plasma renin activity;
- serum DHEAS, testosterone or 17-hydroxyestradiol (virilising or feminising tumour).

Computed tomography (CT) or magnetic resonance imaging (MRI) should be performed in all patients with adrenal masses. The likelihood of an adrenal mass being an adrenocortical carcinoma increases with the size of the mass (25 per cent >4 cm). Adrenal metastases are likely in patients with a history of cancer elsewhere and the sole indications for biopsy of an adrenal mass is to confirm a suspected metastasis from a distant primary site (Summary box 52.1).

Summary box 52.1

Adrenal gland biopsy

- Never biopsy an adrenal mass until pheochromocytoma has been biochemically excluded
- The indication for adrenal gland biopsy is to confirm adrenal gland metastasis

Treatment

The treatment of functional adrenal tumours is described below. Any non-functioning adrenal tumour greater than 4 cm in diameter and smaller tumours that increase in size over time should undergo surgical resection. Non-functioning tumours smaller than 4 cm should be followed-up after 6, 12 and 24 months by imaging (MRI) and hormonal evaluation.

Primary hyperaldosteronism – Conn's syndrome

Incidence

Primary hyperaldosteronism (PHA) is defined by hypertension, as a result of hypersecretion of aldosterone. In PHA, plasma renin activity is suppressed. Among patients with hypertension the incidence of PHA is approximately 2 per cent. Recent studies have revealed that up to 12 per cent of hypertensive patients have PHA with normal potassium levels, thus potassium levels are an inconsistent diagnostic feature of this disease, and cannot be relied on to confirm or exclude it.

Pathology

The most frequent cause of PHA with hypokalaemia is a unilateral adrenocortical adenoma (Figure 52.3). In 20–40 per cent of cases, bilateral micronodular hyperplasia is present. Rare causes of PHA are bilateral macronodular hyperplasia, glucocorticoid-suppressible hyperaldosteronism or adrenocortical carcinoma. In the subset of patients with normokalaemic PHA, 70 per cent have hyperplasia and 30 per cent unilateral adenoma.

Clinical features

Most patients are between 30 and 50 years of age with a female predominance. Apart from hypertension, patients complain of non-specific symptoms: headache, muscle weakness, cramps, intermittent paralysis, polyuria, polydipsia and nocturia.

Diagnosis

The key feature of the biochemical diagnosis is the assessment of potassium level and the aldosterone to plasma renin activity ratio. Antihypertensive and diuretic therapy, which cause

hypokalaemia and influence the renin–angiotensin–aldosterone system, have to be discontinued. Once the biochemical diagnosis is confirmed, MRI or CT should be performed to distinguish unilateral from bilateral disease. Conn's adenomas usually measure between 1 and 2 cm and are detected by CT with a sensitivity of 80–90 per cent (Figure 52.4). Micronodular changes and small adenomas are often underdiagnosed. An apparent unilateral mass could be a non-functioning tumour in a patient with bilateral micronodular hyperplasia. Selective adrenal vein catheterisation can help before a decision on non-surgical or surgical treatment is made. During selective adrenal vein catheterisation, samples are obtained from the vena cava and from both adrenal veins and the aldosterone to cortisol ratio (ACR) is determined in each sample. A significant difference in the ACR ratio on one side indicates unilateral disease.

Treatment

The first-line therapy for PHA with bilateral hyperplasia is medical treatment with spironolactone. In most cases supplemental antihypertensive medication is necessary.

Unilateral laparoscopic adrenalectomy is an effective therapy in patients with clear evidence of unilateral or asymmetrical bilateral disease. A subtotal resection can be considered in the case of a typical single Conn's adenoma. In 10–30 per cent of patients who undergo an adrenalectomy, hypertension persists despite adequate diagnostic work-up and treatment, albeit at a lower level, requiring fewer medications to control it.

Cushing's syndrome

Definition

Hypersecretion of cortisol caused by endogenous production of corticosteroids is known as Cushing's syndrome. It can be either ACTH-dependent or ACTH-independent in origin. The most common cause (85 per cent) of ACTH-dependent Cushing's syndrome is Cushing's disease resulting from a pituitary adenoma that secretes an excessive amount of ACTH. Ectopic ACTH-producing tumours (small cell lung cancer,

Figure 52.3 A Conn's adenoma (arrow) of the left adrenal gland; note the V-shaped normal adrenal tissue.

Figure 52.4 Computed tomography scan of a Conn's adenoma of the left adrenal gland (arrowheads).

foregut carcinoid) and CRH-producing tumours (medullary thyroid carcinoma, neuroendocrine pancreatic tumour) are more infrequent causes of ACTH-dependent Cushing's syndrome. Excessive or prolonged administration of cortisol-like drugs will produce the same clinical picture.

In about 15 per cent of patients, an ACTH-independent Cushing's syndrome (low ACTH levels) is caused by a unilateral adrenocortical adenoma. Adrenocortical carcinoma and bilateral macronodular or micronodular hyperplasia represent rare causes of hypercortisolism.

Clinical symptoms

The clinical features of Cushing's syndrome are shown in Summary box 52.2. The typical patient is characterised by a facial plethora, a buffalo hump and a moon face in combination with hypertension, diabetes and central obesity (Figures 52.5 and 52.6). However, clinical signs can be minimal or absent in patients with subclinical Cushing's syndrome.

Summary box 52.2

Clinical features of Cushing's syndrome

- Weight gain/central obesity
- Diabetes
- Hirsutism
- Hypertension
- Skin changes (abdominal striae, facial plethora, ecchymosis, acne)
- Muscle weakness
- Menstrual irregularity/impotence
- Depression/mania
- Osteoporosis
- Hypokalaemia

Figure 52.5 A 34-year-old patient with Cushing's syndrome whose symptoms included fullness of the face, weight gain and acne. Today, patients with Cushing's syndrome rarely have the full-blown appearance as shown in older textbooks.

Figure 52.6 Discrete central obesity, ecchymosis and fragile skin in a patient with Cushing's syndrome.

Diagnosis

- Morning and midnight plasma cortisol levels are elevated, possibly with loss of diurnal rhythm.
- Dexamethasone fails to suppress 24-hour urinary cortisol excretion.
- Serum ACTH levels discriminate ACTH-dependent from ACTH-independent disease.

Elevated or normal ACTH levels provide evidence for an ACTH-producing pituitary tumour (85 per cent) or ectopic ACTH production. Therefore, in patients with elevated ACTH, MRI of the pituitary gland must be performed. If MRI is negative and additional venous sampling from the inferior petrosal sinus has excluded a pituitary microadenoma, a CT scan of the chest and abdomen is warranted to detect an ectopic ACTH-producing tumour. In patients with suppressed ACTH levels, a CT or MRI scan is performed to assess the adrenal glands.

Subclinical Cushing's syndrome is diagnosed if clinical symptoms are absent in the face of abnormal cortisol secretion.

Treatment

Medical therapy with metyrapone or ketoconazole reduces steroid synthesis and secretion and can be used to prepare patients with severe hypercortisolism preoperatively or if surgery is not possible. ACTH-producing pituitary tumours are treated by trans-sphenoidal resection or radiotherapy. If an ectopic ACTH source is localised, resection will correct hypercortisolism.

A unilateral adenoma is treated by adrenalectomy. In cases of bilateral ACTH-independent disease (Figure 52.7), bilateral adrenalectomy is the primary treatment. Patients with an ectopic ACTH-dependent Cushing's syndrome and an irresectable or unlocalised primary tumour should be considered for bilateral adrenalectomy as this controls hormone excess. Subclinical Cushing's syndrome caused by unilateral adenoma is treated by unilateral adrenalectomy.

Preoperative management

Patients with Cushing's syndrome are at an increased risk of hospital-acquired infection, thromboembolic and myocardial

Figure 52.7 Bilateral asymmetrical hyperplasia of the adrenal glands (arrows) in a patient with Cushing's syndrome.

complications. Therefore, prophylactic anticoagulation and the use of prophylactic antibiotics are essential. Cushing-associated diseases (diabetes, hypertension) must be controlled by medical therapy preoperatively.

Postoperative management

After unilateral adrenalectomy supplemental cortisol should be given postoperatively because the contralateral gland will be suppressed. In total, 15 mg/hour is required parenterally for the first 12 hours followed by a daily dose of 100 mg for 3 days, which is gradually reduced thereafter. After unilateral adrenalectomy, the contralateral suppressed gland needs up to one year to recover adequate function. In 10 per cent of patients with Cushing's disease who undergo a bilateral adrenalectomy after failed pituitary surgery, the pituitary adenoma causes Nelson's syndrome due to continued ACTH secretion at high levels, causing hyperpigmentation as a result of chemical synergies between ACTH and melanocyte-stimulating hormone.

Adrenal metastases

Adrenal metastases are discovered at autopsy in one-third of patients with malignant disease (less frequently during life). In declining frequency, the most common primary tumours are breast, lung, renal, gastric, pancreatic, ovarian and colorectal cancer. In selected circumstances an adrenalectomy is appropriate, for example if it is the sole site of metastatic disease.

Adrenocortical carcinoma

Incidence

Adrenocortical carcinoma is a rare malignancy with an incidence of 1–2 cases per 1 000 000 population per year and a variable but generally poor prognosis. A slight female predominance is observed (1.5:1). The age distribution is bimodal with a first peak in childhood and a second between the fourth and fifth decades.

Pathology

The differentiation between benign and malignant adrenal tumours is challenging, even in the hands of an experienced pathologist. Criteria for malignancy are tumour size, the

presence of necrosis or haemorrhage and microscopic features such as capsular or vascular invasion. These should be assessed in terms of a microscopic diagnostic score. Additional information is provided by immunohistochemistry. The macroscopic features are commonly multinodularity and heterogeneous structure (see Figure 52.8) with haemorrhage and necrosis.

Clinical presentation

Approximately 60 per cent of patients present with evidence of cortisol excess (Cushing's syndrome). Patients with non-functioning tumours frequently complain of abdominal discomfort or back pain caused by large tumours. However, with increasing use of abdominal imaging, a growing number of adrenocortical carcinomas are detected incidentally. Adrenal tumours secreting more than one hormone in excess, or feminising/masculinising steroids are likely to be malignant.

Diagnosis

The diagnostic work-up should include measurements of DHEAS, cortisol and catecholamines to exclude a pheochromocytoma and a dexamethasone suppression test. MRI and CT are equally effective in imaging adrenocortical carcinoma (Figure 52.9). MRI angiography is useful to exclude tumour thrombus in the vena cava. As distant metastases are frequently present, a CT scan of the lungs is recommended. The World Health Organization classification of 2004 is based on the McFarlane classification and defines four stages: tumours <5 cm (stage I) or >5 cm (stage II), locally invasive tumours (III) or tumours with distant metastases (IV). Functioning tumours tend to do worse than non-functioning, but have the advantage of a serum marker which can be used for follow up and disease monitoring.

Treatment

Complete tumour resection (R0) is associated with favourable survival and should be attempted whenever possible. In order to prevent tumour spillage and implantation metastases, the capsule must not be damaged. *En bloc* resection with removal of locally involved organs is often required and in case of tumour thrombus in the vena cava thrombectomy is needed. Laparoscopic adrenalectomy is associated with a high incidence of local recurrence

Figure 52.8 Adrenocortical carcinoma that caused Cushing's syndrome and virilisation in a female patient.

Figure 52.9 Magnetic resonance imaging of adrenocortical carcinoma (arrow) in a patient with cortisol and testosterone excess.

and cannot be recommended. Tumour debulking plays a role in functioning tumours to control hormone excess.

Patients can be treated postoperatively with mitotane alone or in combination with etoposide, doxorubicin and cisplatin. Adjuvant radiotherapy may reduce the rate of local recurrence. After surgery, restaging every three months is required as the risk of tumour relapse is high. Prognosis depends on the stage of disease and complete removal of the tumour. Patients with stage I or II disease have a five-year survival rate of 25 per cent whereas patients with stage III and stage IV disease have five-year survival rates of 6 and 0 per cent, respectively.

Congenital adrenal hyperplasia (adrenogenital syndrome)

Virilisation and adrenal insufficiency in children are pathognomonic of congenital adrenal hyperplasia (CAH). This is an autosomal recessive disorder caused by a variety of enzymatic defects in the synthetic pathway of cortisol and other steroids from cholesterol. The most frequent defect (95 per cent) is the 21-hydroxylase deficiency, which has an incidence of 1 in 5000 live births. Excessive ACTH secretion is caused by the loss of cortisol and this leads to an increase in androgenic cortisol precursors and to CAH. CAH may present in girls at birth with ambiguous genitalia or as late-onset disease at puberty. Hypertension and short stature, caused by the premature epiphyseal plate closure, are common signs. Affected patients are treated by replacement of cortisol and with fludrocortisone. Large hypoplastic adrenals may need to be removed if symptomatic.

Adrenal insufficiency

Primary adrenal insufficiency is caused by the loss of function of the adrenal cortex (Summary box 52.3). It was first described by Thomas Addison in 1855. An early diagnosis is a clinical challenge, even today. Symptoms are only evident when about 90 per cent of the adrenal cortex is destroyed. Secondary adrenal insufficiency is defined as a deficiency of pituitary ACTH secretion. Tertiary adrenal deficiency is provoked by a loss

Summary box 52.3

Diseases associated with adrenal insufficiency

- Polyglandular autoimmune syndrome
- Tuberculosis
- After bilateral adrenalectomy
- Haemorrhage
- Metastases
- Systemic diseases (Boeck's disease, amyloidosis, Wilson's disease)
- Hereditary diseases (e.g. adrenoleukodystrophy, adrenogenital syndrome)
- HIV infection

of hypothalamic CRH secretion and is caused by therapeutic glucocorticoid administration, brain tumour or irradiation.

Acute adrenal insufficiency

Acute adrenal insufficiency usually presents as shock in combination with fever, nausea, vomiting, abdominal pain, hypoglycaemia and electrolyte imbalance. The Waterhouse–Friderichsen syndrome is a bilateral adrenal infarction associated with meningococcal sepsis and is rapidly fatal unless immediately treated. Because of intestinal symptoms and fever, the so-called Addisonian crisis is often misdiagnosed as an acute abdominal condition.

Chronic adrenal insufficiency

When symptoms develop over time, patients present with anorexia, weakness and nausea. As a result of negative feedback, ACTH and pro-opiomelanocortin (POMC) levels increase and cause hyperpigmentation of the skin and oral mucosa. Hypotension, hyponatraemia, hyperkalaemia and hypoglycaemia are commonly observed. The diagnosis of adrenal insufficiency is made using the ACTH stimulation test. Basal ACTH levels are found to be high with cortisol levels decreased. There is no rise in cortisol levels following the exogenous administration of ACTH (synacthen test).

Treatment

If a patient displays features of adrenal insufficiency, treatment must immediately be commenced, before awaiting the biochemical diagnosis. Initial blood samples can be used for later determinations of ACTH and cortisol levels. In addition to intravenous administration of hydrocortisone, 100 mg every 6 hours, 3 litres of saline is given in 6 hours under careful cardiovascular monitoring. Concomitant infections, which are frequently present, require treatment.

Chronic adrenal insufficiency is treated by replacement therapy with daily oral hydrocortisone (10 mg/m² body surface area) and fludrocortisone (0.1 mg). Patients must be advised about the need to take lifelong glucocorticoid and mineralocorticoid replacement therapy. To prevent an Addisonian crisis, patients must be aware of the need to increase the dose in case of illness or stress. If patients with adrenal insufficiency are scheduled for surgery, appropriate steroid cover must be administered.

Thomas Addison, 1795–1860, physician, Guy's Hospital, London, UK, described the effects of disease of the suprarenal capsules in 1849.

Caesar Peter Moller Boeck, 1845–1917, Professor of Medicine, The University of Oslo, Norway.

Samuel Alexander Kinnier Wilson, 1878–1956, Professor of Neurology, King's College Hospital, London, UK, described this condition in 1912.

Rupert Waterhouse, 1875–1958, physician, The Royal United Hospital, Bath, UK, described the syndrome in 1911.

Carl Friderichsen, 1886–1979, Medical Superintendent, Sundby Hospital, Copenhagen, Denmark, gave his account of the syndrome in 1918.

DISORDERS OF THE ADRENAL MEDULLA AND NEURAL CREST-DERIVED TISSUE

Phaeochromocytoma and paraganglioma

Definition

These are tumours of the adrenal medulla and sympathetic ganglia which are derived from chromaffin cells and which produce catecholamines.

Aetiology

The prevalence of phaeochromocytoma in patients with hypertension is 0.1–0.6 per cent with an overall prevalence of 0.05 per cent in autopsy series. In total, 4 per cent of incidentalomas are phaeochromocytomas. Sporadic phaeochromocytomas occur around the fourth decade whereas patients with hereditary forms are diagnosed earlier. Phaeochromocytoma is known as the ‘10 per cent tumour’ as 10 per cent of tumours are inherited, 10 per cent are extra-adrenal, 10 per cent are malignant, 10 per cent are bilateral and 10 per cent occur in children. With the recent advent of detailed genetic tests, however, the incidence of hereditary phaeochromocytomas has been shown to be higher.

Hereditary phaeochromocytomas occur in several tumour syndromes:

- **Multiple endocrine neoplasia type 2 (MEN 2):** an autosomal dominant inherited disorder that is caused by activating germline mutations of the *RET* proto-oncogene.
- **Familial paraganglioma (PG) syndrome:** glomus tumours of the carotid body and extra-adrenal paraganglioma are characteristic in this hereditary tumour syndrome, which is caused by germline mutations within the succinate dehydrogenase complex subunit B (*SDHB*) *SDHD* and *SDHC* genes.
- **von Hippel–Lindau (VHL) syndrome:** those affected can develop early-onset bilateral kidney tumours, phaeochromocytomas, cerebellar and spinal haemangioblastomas and pancreatic tumours. Patients have a germline mutation in the *VHL* gene.
- **Neurofibromatosis (NF) type 1:** phaeochromocytomas in combination with fibromas on the skin and mucosae (‘café-au-lait’ skin spots) are indicative of a germline mutation in the *NF1* gene.

Figure 52.10 Gross appearance of a phaeochromocytoma.

Pathology

Phaeochromocytomas are greyish-pink on the cut surface and are usually highly vascularised. Areas of haemorrhage or necrosis are often observed (Figure 52.10). Microscopically, tumour cells are polygonal but the configuration varies considerably. The differentiation between malignant and benign tumours is difficult, except if metastases are present. An increased PASS (phaeochromocytoma of the adrenal gland scale score), a high number of Ki-67-positive cells, vascular invasion or a breached capsule all lean more towards malignant rather than benign.

Phaeochromocytomas may also produce calcitonin, ACTH, vasoactive intestinal polypeptide (VIP) and parathyroid hormone-related protein (PTHrP). In patients with MEN 2, the onset of phaeochromocytoma is preceded by adrenomedullary hyperplasia, sometimes bilateral. Phaeochromocytoma is rarely malignant in MEN 2.

Clinical features

Symptoms and signs are caused by catecholamine excess and are typically intermittent (Table 52.2). In total, 90 per cent of patients with the combination of headache, palpitations and sweating have a phaeochromocytoma. Paroxysms may be precipitated by physical training, induction of general anaesthesia and numerous drugs and agents (contrast media, tricyclic antidepressive drugs, metoclopramide and opiates). Hypertension may occur continuously, be intermittent or absent. A subset of patients are asymptomatic. More than 20 per cent of apparently sporadic phaeochromocytomas are caused by germline mutations in the *RET*, *SDHB*, *SDHC*, *SDHD* and *NF1* genes; genetic testing for these genes is therefore recommended, particularly in those aged under 50 years.

Table 52.2 Clinical signs of phaeochromocytoma.

Symptoms	Prevalence (%)
Hypertension	80–90
Paroxysmal	50–60
Continuous	30
Headache	60–90
Sweating	50–70
Palpitation	50–70
Pallor	40–45
Weight loss	20–40
Hyperglycaemia	40
Nausea	20–40
Psychological effects	20–40

Diagnosis

The first step in the diagnosis of a phaeochromocytoma is the determination of adrenaline and noradrenaline breakdown products, metanephrine and normetanephrine level, in a 12- or 24-hour urine collection. Levels that exceed the normal range by 2–40 times will be found in affected patients. Determination of plasma-free metanephrine and normetanephrine levels also

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany.
Arvid Lindau, 1892–1958, Professor of Pathology, Lund, Sweden.

has a high sensitivity. Biochemical tests should be performed at least twice. The biochemical diagnosis is followed by the localisation of the phaeochromocytoma. MRI is preferred because contrast media used for CT scans can provoke paroxysms. Classically, phaeochromocytomas show a 'Swiss cheese' configuration (Figure 52.11). ^{123}I -MIBG (metaiodobenzylguanidine) single-photon emission computed tomography (SPECT) will identify about 90 per cent of primary tumours and is essential for the detection of multiple extra-adrenal tumours and metastases (Figure 52.12). PET scanning using FDG PET or DOPA PET is yet more sensitive in detecting metastatic foci.

Treatment

Laparoscopic resection is now routine in the treatment of phaeochromocytoma. If the tumour is larger than 8–10 cm or radiological signs of malignancy are detected, an open approach should be considered.

Preoperative

Once a phaeochromocytoma has been diagnosed, an α -adrenoreceptor blocker (phenoxybenzamine) is used to block

catecholamine excess and its consequences during surgery. With adequate medical pretreatment, the perioperative mortality rate has decreased from 20–45 per cent to less than 3 per cent. A dose of 20 mg of phenoxybenzamine initially should be increased daily by 10 mg until a daily dose of 100–160 mg is achieved and the patient reports symptomatic postural hypotension. Additional β -blockade is required if tachycardia or arrhythmias develop; this should not be introduced until the patient is α -blocked.

With adequate α -blockade preoperatively, anaesthesia should not be more hazardous than in patients with a non-functioning adrenal tumour; however, in some patients, dramatic changes in heart rate and blood pressure may occur and require sudden administration of pressor or vasodilator agents. A central venous catheter and invasive arterial monitoring are used. Special attention is required when the adrenal vein is ligated as a sudden drop in blood pressure may occur. The infusion of large volumes of fluid or administration of noradrenaline can be necessary to correct postoperative hypotension in the presence of unopposed α -blockade.

Postoperative

Patients should be observed for 24 hours in the intensive care or high dependency unit as hypovolaemia and hypoglycaemia may occur. Lifelong yearly biochemical tests should be performed to identify recurrent, metastatic or metachronous phaeochromocytoma (Summary box 52.4).

Figure 52.11 Magnetic resonance imaging of a sporadic phaeochromocytoma of the left adrenal gland (arrowheads).

Figure 52.12 Metaiodobenzylguanidine (MIBG) single-photon emission computed tomography scan of a phaeochromocytoma of the left adrenal gland (arrow) in the same patient as in Figure 52.11.

Summary box 52.4

Phaeochromocytoma

- Obtain a secure biochemical diagnosis
- Exclude family history
- Diagnosis confirmed, treat with α -blockers
- Plan surgical excision
- Yearly lifelong follow up

Malignant phaeochromocytoma

Definition

Approximately 10 per cent of phaeochromocytomas are malignant. This rate is higher in extra-adrenal tumours (paragangliomas). The diagnosis of malignancy implies metastases of chromaffin tissue, most commonly to lymph nodes, bone and liver.

Treatment

Surgical excision is the only chance for cure. Even in patients with metastatic disease, tumour debulking can be considered to reduce the tumour burden and to control the catecholamine excess. Symptomatic treatment can be obtained with α -blockers. Mitotane should be started as adjuvant or palliative treatment. Treatment with ^{131}I -MIBG or combination chemotherapy has resulted in a partial response in 30 per cent and an improvement of symptoms in 80 per cent of patients. The natural history is highly variable with a five-year survival rate of less than 50 per cent.

Phaeochromocytoma in pregnancy

Phaeochromocytomas in pregnancy may imitate an amnion infection syndrome or pre-eclampsia. Without adequate α -blockade,

mother and unborn child are threatened by hypertensive crisis during delivery. In the first and second trimesters, the patient should be scheduled for laparoscopic adrenalectomy after adequate α -blockade; the risk of a miscarriage during surgery is high. In the third trimester, elective Caesarean with **consecutive** adrenalectomy should be performed. The maternal mortality rate is 50 per cent when a pheochromocytoma remains undiagnosed.

Neuroblastoma

Definition

A neuroblastoma is a malignant tumour that is derived from the sympathetic nervous system in the adrenal medulla (38 per cent) or from any site along the sympathetic chain in the paravertebral sites of the abdomen (30 per cent), chest (20 per cent) and, rarely, the neck or pelvis.

Pathology

Neuroblastomas have a pale and grey surface, are encapsulated and show areas with calcification. With increased tumour size, necrosis and haemorrhage may be detected. They are characterised by the presence of immature cells derived from the neuroectoderm of the sympathetic nervous system. Mature cells are found only in ganglioneuroblastomas.

Clinical features

Predominantly, newborn infants and young children (<5 years of age) are affected. Symptoms are caused by tumour growth or by bone metastases. Patients present with a mass in the abdomen, neck or chest, proptosis, bone pain, painless bluish skin metastases, weakness or paralysis. Metastatic disease is present in 70 per cent of patients at presentation.

Diagnosis

Biochemical evaluation should include urinary excretion (24-hour urine) of vanillylmandelic acid (VMA), homovanillic acid (HVA), dopamine and noradrenaline, as increased levels are present in about 80 per cent of patients. Accurate staging requires CT/MRI of the chest and abdomen, a bone scan, bone marrow aspiration and core biopsies as well as an MIBG scan. Staging is established according to the International Neuroblastoma Staging System (INSS).

Treatment

Prognosis can be predicted by the tumour stage and the age at diagnosis. Patients are classified as low, intermediate or high risk. Low-risk patients are treated by surgery alone (the addition of 6–12 weeks of chemotherapy is optional) whereas intermediate-risk patients are treated by surgery with adjuvant multi-agent chemotherapy (carboplatin, cyclophosphamide, etoposide, doxorubicin). High-risk patients receive high-dose multiagent chemotherapy followed by surgical resection in responding tumours and myeloablative stem cell rescue. Patients assigned to the low-risk, intermediate-risk and high-risk groups have overall three-year survival rates of 90, 70–90 and 30 per cent, respectively.

Ganglioneuroma

Definition

A ganglioneuroma is a benign neoplasm that arises from neural crest tissue. Ganglioneuromas can occur in the adrenal medulla

and are characterised by mature sympathetic ganglion cells and Schwann cells in a fibrous stroma.

Clinical features

Ganglioneuroma is found in all age groups but is more common before the age of 60. Ganglioneuromas occur anywhere along the paravertebral sympathetic plexus and in the adrenal medulla (30 per cent). Most often they are identified incidentally by CT or MRI performed for other indications.

Treatment

Treatment is by surgical excision, laparoscopic when adrenalectomy is indicated.

SURGERY OF THE ADRENAL GLANDS

Since its introduction in the 1990s, laparoscopic or retroperitoneoscopic adrenalectomy has become the 'gold standard' in the resection of adrenal tumours, except for tumours with signs of malignancy. The more popular approach is the laparoscopic transperitoneal approach, which offers a better view of the adrenal region than open surgery. The advantage of the retroperitoneoscopic approach is the minimal dissection required by this extra-abdominal procedure. In the case of small, bilateral tumours or in patients with hereditary tumour syndromes a subtotal resection is warranted, to avoid steroid dependence. The mortality rate ranges from 0 to 2 per cent in specialised centres.

An open approach should be considered if radiological signs, distant metastases, large tumours (>8–10 cm) or a distinct hormonal pattern suggest malignancy.

Laparoscopic adrenalectomy

Knowledge of the anatomy of the adrenal region is essential as anatomical landmarks guide the surgeon during operation. If these landmarks are respected, injury to the vena cava or renal vein, the pancreatic tail or the spleen can be avoided. Careful haemostasis is essential as small amounts of blood can impair the surgeon's view. To prevent tumour spillage, direct grasping of the adrenal tissue/tumour has to be avoided.

Right adrenalectomy

Position the patient right side up, with table brake. Use three ports to start. The dissection starts at the level of the periadrenal fat using careful coagulation and the peritoneum should be divided 2 cm below the edge of the liver from medial (inferior vena cava) to the lateral abdominal wall (Figure 52.13). This flap of peritoneum can then be used to retract the liver up and off the adrenal. A fourth port may be useful to hold the liver up. Identify the gland and mobilise gently, securing the vein with a clip or using one of the available energy devices, and remove the gland in a plastic catch bag.

Left adrenalectomy

With the patient positioned on his or her right side, mobilisation of the spleen will displace the pancreatic tail medially. The incision of Gerota's fascia is followed by identification of the adrenal vein, which runs into the renal vein in the space between the medial aspect of the kidney and the posterior aspect of the pancreatic tail. The resection is completed by mobilising

Figure 52.13 Laparoscopic view during a right adrenalectomy. Arrow indicates the adrenal vein. AT, adrenal tumour; VC, vena cava.

the adrenal gland at the level of the periadrenal fat. Remove the gland in a bag and close the three port sites after infiltrating each with local anaesthesia.

Retroperitoneoscopic adrenalectomy

The first port is placed at the distal end of the 12th rib with the patient in the prone position. After a digital dissection into the retroperitoneum, Gerota's fascia is displaced ventrally. The right adrenal vein is covered by the retrocaval posterior aspect of the adrenal gland. The left adrenal vein is usually located at the medial inferior pole of the adrenal gland. High inflation pressures allow bloodless dissection effectively tamponading the veins. Being outside the abdominal cavity affords an excellent view.

Open adrenalectomy

An open adrenalectomy is almost exclusively performed when a malignant adrenal tumour is suspected. On the right side, the hepatic flexure of the colon is mobilised and the right liver lobe is cranially retracted to achieve an optimal exposure of the inferior vena cava and the adrenal gland. On the left side, the adrenal gland can be exposed after mobilisation of the splenic flexure of the colon, through the transverse mesocolon or through the gastrocolic ligament. The remaining dissection is the same as in laparoscopic adrenalectomy. A resection of regional lymph nodes is recommended in malignant adrenal tumours and should include resection of the tissue between the renal pedicle and the diaphragm.

PANCREATIC ENDOCRINE TUMOURS

Introduction

Pancreatic endocrine tumours (PET) represent an important subset of pancreatic neoplasms. They account for 5 per cent of all clinically detected pancreatic tumours. They consist of single or multiple, benign or malignant neoplasms and are associated in 10–20 per cent of cases with multiple endocrine neoplasia type

Figure 52.14 Immunofluorescent labelling of endocrine (insulin (green)) and exocrine (amylase (red)) pancreatic cells and the nuclear marker DAPI (blue) (courtesy of Dr Esni, Department of Surgery, University of Pittsburgh, USA).

1 (MEN 1). They present as either functional tumours, causing specific hormonal syndromes, or non-functional tumours, with symptoms similar to those in patients with pancreatic adenocarcinoma. This section focuses on insulinomas, gastrinomas and non-functioning tumours because they represent 90 per cent of all PET (Table 52.3).

Function of the endocrine pancreas

The endocrine cells of the pancreas are grouped in the islets of Langerhans, which constitute approximately 1–2 per cent of the mass of the pancreas (Figure 52.14). There are about one million islets in a healthy adult human pancreas and their combined weight is 1–1.5 g. There are four main types of cell in the islets of Langerhans, which can be classified according to their secretions:

- 1 beta cells producing insulin (65–80 per cent of the islet cells);
- 2 alpha cells producing glucagon (15–20 per cent);
- 3 delta cells producing somatostatin (3–10 per cent);
- 4 pancreatic polypeptide (PP) cells containing polypeptide (1 per cent).

Insulinoma

Definition

This is an insulin-producing tumour of the pancreas causing the clinical scenario known as Whipple's triad, i.e. symptoms of hypoglycaemia after fasting or exercise, plasma glucose levels <2.8 mmol/L and relief of symptoms on intravenous administration of glucose.

George Hoyt Whipple, 1878–1976, Professor of Pathology, University of Rochester, Rochester, NY, USA, described this disease in 1907. He shared the 1934 Nobel Prize for Physiology or Medicine with George Richards Minot and William Parry Murphy 'for their discoveries concerning liver therapy against anaemias'.

Table 52.3 Neuroendocrine tumours of the pancreas.

Tumour (syndrome)	Incidence (%)	Presentation	Malignancy (%)
Insulinoma	70–80	Weakness, sweating, tremor, tachycardia, anxiety, fatigue, dizziness, disorientation, seizures	<10
Gastrinoma	20–25	Intractable or recurrent peptic ulcer disease (haemorrhage, perforation), complications of peptic ulcer, diarrhoea	60–80
Non-functional tumours	30–50	Obstructive jaundice, pancreatitis, epigastric pain, duodenal obstruction, weight loss, fatigue	60–90
VIPoma	4	Profuse watery diarrhoea, hypotension, abdominal pain	80
Glucagonoma	4	Migratory necrolytic skin rash, glossitis, stomatitis, angular cheilitis, diabetes, severe weight loss, diarrhoea	80
Somatostatinoma	<5	Cholelithiasis, diarrhoea, neurofibromatosis	50
Carcinoid	<1	Flushing, sweating, diarrhoea, oedema	90
ACTHoma	<1	Cushing's syndrome	>90
GRFoma	<1	Acromegaly	30

ACTH, adrenocorticotrophic hormone; GRF, growth hormone-releasing factor; VIP, vasoactive intestinal polypeptide.

Incidence

Insulinomas are the most frequent of all the functioning PETs with a reported incidence of 2–4 cases per million population per year. Insulinomas have been diagnosed in all age groups with the highest incidence found in the fourth to the sixth decades. Women seem to be slightly more frequently affected.

Pathology

The aetiology and pathogenesis of insulinomas are unknown. No risk factors have been associated with these tumours. Virtually all insulinomas are located in the pancreas and tumours are equally distributed within the gland. Approximately 90 per cent are solitary and about 10 per cent are multiple and associated with MEN 1 syndrome.

Prognosis and predictive factors

No markers are available that reliably predict the biological behaviour of an insulinoma. Approximately 10 per cent are malignant. Insulinomas of <2 cm in diameter without signs of vascular invasion or metastases are considered benign.

Clinical features

Insulinomas are characterised by fasting hypoglycaemia and neuroglycopenic symptoms. The episodic nature of the hypoglycaemic attacks is caused by intermittent insulin secretion by the tumour. This leads to central nervous system symptoms such as diplopia, blurred vision, confusion, abnormal behaviour and amnesia. Some patients develop loss of consciousness and coma. The release of catecholamines produces symptoms such as sweating, weakness, hunger, tremor, nausea, anxiety and palpitations.

Biochemical diagnosis

A fasting test that may last for up to 72 hours is regarded as the most sensitive test. Usually, insulin, proinsulin, C-peptide and blood glucose are measured in 1- to 2-hour intervals to demonstrate inappropriately high secretion of insulin in relation to blood glucose. About 80 per cent of insulinomas are diagnosed by

this test, most of them in the first 24 hours. Elevated C-peptide levels demonstrate the endogenous secretion of insulin and exclude factitious hypoglycaemia caused by insulin injection.

Differential diagnosis

The differential diagnosis of hypoglycaemia includes hormonal deficiencies, hepatic insufficiency, medication, drugs and enzyme defects. Occasionally, differentiating insulinoma from other causes of hypoglycaemia can be difficult. Nesidioblastosis is a rare disorder, mainly encountered in children, which is characterised by replacement of normal pancreatic islets by diffuse hyperplasia of islet cells.

Medical treatment of insulinoma

Medical management is reserved only for patients who are unable or unwilling to undergo surgical treatment or for unresectable metastatic disease. Diazoxide suppresses insulin secretion by direct action on the beta cells and offers reasonably good control of hypoglycaemia in approximately 50 per cent of patients. When surgical options to treat malignant insulinomas cannot be applied, chemotherapeutic options include doxorubicin and streptozotocin.

Surgical treatment of insulinoma

Indications for operation

After a positive fasting test and exclusion of diffuse abdominal metastases by ultrasound or CT scan, all patients should be advised to undergo surgical excision of insulinoma.

Preoperative localisation studies

Intraoperative exploration of the pancreas is the best method to use for localisation of insulinoma, yet the operating surgeon will need preoperative localisation! Insulinomas are detected in about 65 per cent of cases by endoscopic ultrasound (EUS), 33 per cent of cases by CT scan and abdominal ultrasound and 15 per cent of cases by magnetic resonance tomography. Intraoperative ultrasound (IOUS) of the pancreas is a vital tool

Figure 52.15 (a) Intraoperative ultrasound showing a typical insulinoma (dashed circle). v portae, portal vein; v cava inf, inferior vena cava; d wirsung, pancreatic duct. (b) Enucleated insulinoma.

after mobilisation of the gland. For preoperative localisation of an insulinoma, EUS has the highest sensitivity and should be used if laparoscopic resection is considered. If no lesion is identified and one can rely on the biochemical tests for diagnosis, laparotomy should follow, using IOUS.

Benign insulinoma

Surgical cure rates in patients with the biochemical diagnosis of insulinoma range from 90 to 100 per cent. At open surgery an extended Kocher manoeuvre and mobilisation of the head and then the distal pancreas is performed to explore the whole

Figure 52.16 Laparoscopic enucleation of an insulinoma.

gland. IOUS should then be used to confirm the presence of a tumour, to find non-palpable lesions and also to identify the relation of the tumour to the pancreatic duct (Figure 52.15a). Tumour enucleation is the technique of choice (Figure 52.15b). For superficial tumours, laparoscopic enucleation is undertaken (Figure 52.16). Tumours located deep in the body or tail of the pancreas and those in close proximity to the pancreatic duct require distal pancreatectomy. Postoperatively, blood sugar levels begin to rise in most patients within the first few hours after removal of the tumour. To preserve pancreatic function and reduce the risk of iatrogenic diabetes mellitus, patients in whom tumour localisation is not successful at operation should not undergo blind resection.

Malignant insulinoma

Aggressive attempts at resection are recommended as these tumours are much less virulent than adenocarcinomas.

Gastrinoma (Zollinger–Ellison syndrome)

Definition

Zollinger–Ellison syndrome (ZES) is a condition that includes: (1) fulminating ulcer diathesis in the stomach, duodenum or atypical sites; (2) recurrent ulceration despite ‘adequate’ therapy; and (3) non-beta islet cell tumours of the pancreas (gastrinoma).

Incidence

Gastrinomas account for about 20 per cent of PETs, second in frequency to insulinomas. Approximately 0.1 per cent of patients with duodenal ulcers have evidence of ZES. The reported incidence is between 0.5 and 4 cases per million population per year. ZES is more common in males than in females. The mean age at the onset of symptoms is 38 years, and the range is 7–83 years.

Pathology

The aetiology and pathogenesis of sporadic gastrinomas are unknown. At the time of diagnosis more than 60 per cent of tumours are malignant. Pancreatic gastrinomas are mainly found in sporadic disease; most are found in the head of the pancreas. More than 70 per cent of the gastrinomas in MEN 1 syndrome and most sporadic gastrinomas are located in the first and second part of the duodenum. Therefore, the anatomical area comprising the head of the pancreas, the superior and descending portion of the duodenum and the relevant lymph nodes has been called the ‘gastrinoma triangle’ because it harbours the vast majority of these tumours (Figure 52.17). All patients with gastrinomas should be tested for MEN 1 syndrome.

Prognosis and predictive factors

In general, the progression of gastrinomas is relatively slow with a five-year survival rate of 65 per cent and a ten-year survival rate of 51 per cent. Patients with complete tumour resection have excellent five- and ten-year survival rates (90–100 per cent). Patients with pancreatic tumours have a worse prognosis than those with primary tumours in the duodenum. There is no established marker to predict the biological behaviour of gastrinoma.

Clinical and biochemical features

Over 90 per cent of patients with gastrinomas have peptic ulcer disease, often multiple or in unusual sites. Diarrhoea is another

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland. In 1909 he was awarded the Nobel Prize for Physiology or Medicine for his work on the thyroid.

Robert Milton Zollinger, 1903–1992, Professor of Surgery, Ohio State University, Columbus, OH, USA.

Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, WI, USA.

Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at Ohio State University.

Figure 52.17 The gastrinoma triangle.

common symptom, caused by the large volume of gastric acid secretion. Abdominal pain from either peptic ulcer disease or gastro-oesophageal reflux disease (GORD) remains the most common symptom, occurring in more than 75 per cent of patients.

Biochemical diagnosis

If the patient presents with a gastric pH below 2.5 and a serum gastrin concentration above 1000 pg/mL (normal <100 pg/mL) then the diagnosis of ZES is confirmed. Unfortunately, the majority of patients have serum gastrin concentrations between 100 and 500 pg/mL and in these patients a secretin test should be performed. The secretin test is considered positive if an increase in serum gastrin of >200 pg/mL over the pretreatment value is obtained; this also rules out other causes of hypergastrinaemia (e.g. atrophic gastritis).

Differential diagnosis

The most common misdiagnoses are idiopathic peptic ulcer disease, chronic idiopathic diarrhoea and GORD. Other reasons for hypergastrinaemia are chronic atrophic gastritis, gastric outlet stenosis and retained antrum after gastric resection.

Medical treatment of gastrinoma

In most patients with ZES, gastric hypersecretion can be treated effectively with proton pump inhibitors. Octreotide can also help to control acid hypersecretion. Systemic chemotherapy is utilised in patients with diffuse metastatic gastrinomas. Streptozotocin in combination with 5-fluorouracil or doxorubicin is the first-line treatment.

Surgical treatment of gastrinoma

Indications for operation

Surgical exploration should be performed in all patients without diffuse metastases, to remove known malignant gastrinomas or benign ones.

Preoperative localisation studies

Pancreatic gastrinomas are often larger than 1 cm in diameter

whereas gastrinomas of the duodenum are usually smaller. Therefore, it is nearly impossible to identify duodenal gastrinomas by preoperative imaging. Pancreatic gastrinomas are detected by EUS in about 80–90 per cent of cases, by CT in 39 per cent of cases and by MRI in 46 per cent of cases. In approximately one-third of patients, the results of conventional imaging studies are negative. On the basis of recent studies, either EUS or CT and somatostatin receptor scintigraphy (SRS) should be performed preoperatively for staging.

Pancreatic gastrinomas

Most pancreatic gastrinomas are solitary, located in the head of the gland or uncinate process, and can be identified at operation. Enucleation with peripancreatic lymph node dissection is the procedure of choice. Rarely, tumours are situated in the body or tail and should be treated by enucleation or distal resection. Even if a tumour is found in the pancreas, duodenotomy is recommended to detect additional tumours, if the patient has MEN 1.

Duodenal gastrinomas

The duodenum should be opened with a longitudinal incision and the posterior and anterior walls palpated separately (Figure 52.18). Duodenal tumours smaller than 5 mm can be enucleated with the overlying mucosa; larger tumours are excised with full-thickness excision of the duodenal wall.

Non-functional endocrine pancreatic tumours

Definition

PETs are clinically classified as non-functioning PETs (NF-PETs) when they do not cause a clinical syndrome.

Incidence

NF-PETs account for 30–50 per cent of all PETs. They are most often diagnosed in the fifth to sixth decades of life.

Pathology

NF-PETs cannot be differentiated from functional tumours by immunocytochemistry because they may also express hormones such as gastrin, insulin, etc. They usually stain positively for

Figure 52.18 Palpation of a duodenal gastrinoma (arrow) after duodenotomy.

chromogranin A and synaptophysin. The tumours are usually large (>5 cm) and unifocal except in MEN 1 syndrome. They are distributed throughout the pancreas with a head to body to tail ratio of 7:1:1.5.

Prognosis and predictive factors

About 70 per cent of all NF-PETs are malignant. Overall five- and ten-year survival rates of 65 and 49 per cent, respectively, have been described. When comparing NF-PETs with functioning PETs, the NF-PETs have a worse prognosis.

Clinical features

Patients usually present late because of the lack of a clinical/hormonal marker of tumour activity. Therefore, in contrast to functioning PETs, patients with NF-PETs present with various non-specific symptoms, including jaundice, abdominal pain, weight loss and pancreatitis. In some cases liver metastases are the first presentation.

Biochemical diagnosis

Increased levels of chromogranin A have been reported in 50–80 per cent of NF-PETs; the level of chromogranin A sometimes correlates with the tumour burden. The combination of elevated chromogranin A and PP measurements increases the sensitivity of diagnosis from 84 to 96 per cent in NF-PETs.

Differential diagnosis

Differentiation from the more aggressive pancreatic adenocarcinoma is extremely important (Table 52.4). Recognition of NF-PETs is imperative because of their resectability and excellent long-term survival compared with their exocrine counterparts.

Table 52.4 Differences between pancreatic cancer and non-functioning endocrine pancreatic tumours (NF-PETs).

	Pancreatic cancer	NF-PETs
Tumour size	<5 cm	>5 cm
Computed tomography scan	Hypodensity	Hyperdensity
	No calcifications	Calcifications possible
Chromogranin A in blood	Negative	Positive
Somatostatin receptor scintigraphy	Negative	Positive

Medical treatment of non-functioning islet cell tumours

When surgical excision is not possible, chemotherapeutic options include streptozotocin, octreotide and interferon.

Surgical treatment of non-functioning islet cell tumours

Indications for operation

An aggressive surgical approach should be considered in malignant NF-PETs, even in the presence of distant metastases.

Preoperative localisation studies

Preoperative ultrasound or CT scan are the procedures of choice as these tumours are relatively large. Also, SRS should be performed to differentiate endocrine from non-endocrine pancreatic tumours.

Operative procedures

The major goal is a potentially curative resection. This may require partial pancreaticoduodenectomy as well as the synchronous or metachronous resection of liver metastases. Using an aggressive approach, curative resections are possible in up to 62 per cent of cases and overall five-year survival rates of around 65 per cent can be achieved. Repeated resections for resectable recurrences or metastases are justified to improve survival.

NEUROENDOCRINE TUMOURS OF THE STOMACH AND SMALL BOWEL

Definition and physiology

Neuroendocrine tumours (NET) of the gut and the pancreas arise from the diffuse neuroendocrine cell system, which can be found as single or clustered cells in the mucosa of the bronchi, stomach, gut, biliary tree, urogenital system and in the pancreas (see Chapters 71, 69 and 72 for NET of the appendix, colon and rectum, respectively). This cell system was first recognised as the 'clear cell system' by Feyrter in the 1930s and is identical to the APUD (amine precursor uptake and decarboxylation) system described by Pearse in 1970. All cells of the system secrete different neuroendocrine markers, such as synaptophysin, chromogranin A and neurone-specific enolase (NSE), and produce peptide hormones that are stored in granules, e.g. serotonin, somatostatin, PP or gastrin. In clinical practice chromogranin A is utilised as a tumour marker. The main functional test for NET of the jejunum and ileum (the NET that are most often encountered) is the measurement of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in urine.

Pathology

Neuroendocrine cells can form hyperplasias or tumours. In 1907, Oberndorfer coined the term 'carcinoids' for tumours arising from these cells. Although the term carcinoid continues to be used in clinical practice, these tumours do not always grow in a well-differentiated pattern reflecting the rather benign 'carcinoma-like', i.e. 'carcinoid', tumour. They can show different growth patterns, from benign tumours to high-grade undifferentiated carcinomas having a poor prognosis (neuroendocrine carcinomas). Therefore, they should always be addressed as NET, including a description of their histological pattern (benign, low- or high-grade malignant) and their anatomical site (e.g. stomach, ileum) according to the World Health Organization classification (2000). The relative distribution of NET in different organs is given in Table 52.5. Another classification based on embryological principles classifies NET as foregut (lung, stomach, pancreas), midgut (small bowel and appendix) and hindgut (colon and rectum) tumours.

Neuroendocrine tumours of the stomach

These tumours are rare. They comprise about 5 per cent of all NET of the gastrointestinal tract and have an incidence of

Table 52.5 Relative distribution of neuroendocrine tumours in different organs.

Site	Distribution (%)
Lung	10
Stomach	5
Duodenum	2
Small bowel	25
Appendix	40
Colon	6
Rectum	15

approximately 0.2 cases per 100 000 population per year. There are four different types of gastric NET (Table 52.6). Types 1 and 2 are small benign tumours that arise from the enterochromaffin-like (ECL) cells in the gastric mucosa and grow in either a linear or a nodular pattern (Figure 52.19). Hypergastrinaemia may cause symptoms and the treatment of choice is endoscopic resection. Types 3 and 4 are almost always malignant and surgical resection should be undertaken if possible.

Pathogenesis, diagnosis and treatment

Type 1 tumours (ECLomas) are the most frequent NET of the stomach (approximately 80 per cent); they occur mostly in elderly women. Chronic hypergastrinaemia is the result of chronic atrophic gastritis and achlorhydria, the alkaline pH being the stimulus for hypersecretion of gastrin. They do not cause symptoms and are usually detected during gastroscopy for other reasons. Endoscopic resection is the treatment of choice. Antrectomy and resection of ECLomas should be undertaken only if there is recurrent disease and multiple (more than six) tumours, with at least one measuring >1 cm and infiltration of at least one into the submucosa.

The pathogenesis, diagnosis and treatment of type 2 tumours is similar to that of type 1. The only difference is the cause of the hypergastrinaemia, which in type 2 tumours is the result of MEN 1 syndrome, with multiple gastrinomas in the duodenum or, rarely, in the pancreas.

Type 3 tumours are rare, sporadic and solitary tumours of

**Figure 52.19** Immunostaining of chromogranin in micronodular hyperplasia of enterochromaffin-like (ECL) cells of the stomach associated with chronic atrophic gastritis.

unknown origin. Serum gastrin is normal; upper gastrointestinal bleeding is the usual symptom that leads to endoscopy. Type 3 tumours are usually larger than 2 cm and often have lymph node and liver metastases at the time of diagnosis. Gastrectomy and lymph node dissection and resection of liver metastases is the treatment of choice. Liver metastases can also be treated by chemoembolisation.

Type 4 tumours present as large ulcerating malignancies similar to adenocarcinomas and should be treated accordingly. The prognosis of types 3 and 4 is poor (Table 52.6).

Neuroendocrine tumours of the small bowel

Introduction

These are the tumours that are most commonly referred to as 'carcinoid' tumours, as most NET of the gastrointestinal tract are found in the small bowel. They are also called 'midgut' tumours (together with NET of the appendix and the right colon). These tumours produce serotonin and cause the 'carcinoid' syndrome, but only in patients who have a large volume of liver metastases or if there is advanced local tumour growth draining into the

Table 52.6 Classification of gastric neuroendocrine tumours.

Type	Histological pattern	Size and location	Causative factor and prognosis
1	Benign, non-functional, well differentiated	Gastric corpus; <1 cm; mucosa/submucosa	ECLomas in chronic atrophic gastritis, hypergastrinaemia
2	Benign or low-grade malignant, differentiated	1–2 cm; angioinvasion; mucosa/submucosa	ECLomas with hypergastrinaemia as a result of gastrinoma in MEN 1
3	Low-grade malignant, differentiated	2 cm; invasion beyond submucosa	Sporadic ECLomas not related to hypergastrinaemia
4	Intermediate or small cell type, high-grade malignant (neuroendocrine carcinoma)	Different sizes	Causative factor unknown; prognosis poor

ECL, enterochromaffin-like; MEN, multiple endocrine neoplasia.

inferior vena cava and thereby bypassing the liver. NET of the duodenum (gastrinomas in MEN 1 syndrome, somatostatinomas and others) are very rare and are not discussed further.

Pathology

NET of the jejunum and ileum arise from a subgroup of cells of the diffuse neuroendocrine system, the enterochromaffin (EC) cells, which secrete serotonin and substance P. They are either solitary or more often multiple, are almost always malignant and metastasise early to the regional lymph nodes and the liver depending on the location of the primary tumour(s) (Figure 52.20).

Clinical symptoms

Symptoms that lead to the diagnosis are caused by either the primary tumour or its lymph node metastases. Acute or chronic, recurrent or persistent abdominal pain, ileus or, rarely, lower gastrointestinal bleeding may occur. Symptoms may be due to liver metastases, such as sudden painful reddening of the face and chest ('flushing'), diarrhoea or bronchospasm. These symptoms constitute 'carcinoid' syndrome. About 60 per cent of patients eventually develop cardiac symptoms because of stenosis and insufficiency of the pulmonary and, more rarely, the tricuspid valve, with enlargement and thickening of the wall of the right atrium. The aetiology is unknown but local effects of serotonin and kinins may contribute.

Abdominal symptoms are caused either by obstruction of the appendix by an appendiceal NET (leading to appendectomy) or by obstruction of the mesentery or the bowel lumen by growth of lymph node metastases in the mesentery near the bowel. Pain is caused by chronic ischaemia of the bowel (Figure 52.21), resulting not only from mesenteric lymph node metastases but also from constriction of mesenteric arteries and fibrosis of the mesentery by a so-called desmoplastic reaction.

Primary tumours in the jejunum and ileum rarely cause symptoms such as bleeding or intussusception as they usually only measure from a few millimetres up to 1 cm or at the most 2 cm in diameter (Figure 52.22). A polypoid NET of the terminal ileum may, however, cause ileocaecal intussusception.

Diagnosis

The diagnosis of NET of the small bowel is made by history, physical examination of the abdomen, imaging and an assessment

Figure 52.20 Relation of site and diameter of neuroendocrine tumours of the gut to frequency of lymph node metastasis.

of 5-HIAA in a 24-hour urine sample. It is positive in larger tumours only if metastases are present. Cross-sectional imaging, sonography, CT scan and MRI may show the primary tumour, mesenteric lymph node and liver metastases.

The best method for staging of NET is an octreotide (SRS) scan. This will show all tumour deposits provided that they are large enough and have a high somatostatin receptor density (Figure 52.23).

Surgical procedure

Surgery should be undertaken as soon as the diagnosis is made, even in the presence of liver metastases. The main goal is resection of the bowel primary tumour(s) and mesenteric lymph node metastases. This may entail resection of large amounts of bowel (100 cm or more), particularly if stage III or IV lymph node masses are found in the mesentery (Figure 52.24). In the presence of liver metastases, extrahepatic disease should be resected whenever possible. Metastatic disease in the mesenteric root will lead to long-term pain in the abdomen or back and to a poor quality of life, whereas liver metastases can be treated by chemotherapy or embolisation.

Figure 52.21 Chronic ischaemia of the small bowel caused by desmoplastic reaction and narrowing of vessels in the mesentery in a neuroendocrine tumour of the ileum.

Figure 52.22 Multiple neuroendocrine tumours in the small bowel causing large lymph node metastases in the mesentery.

Figure 52.23 Octreotide scan of a patient with neuroendocrine tumour of the gut and diffuse metastases in different organs.

Figure 52.24 Bulky lymph node metastases can occur at different levels in the mesentery. To resect them completely, long segments of bowel must be resected, the closer to the mesenteric root the metastases are situated (adapted from Akerström, G., Hellman, P. and Öhrvall, U. (2001) Midgut and hindgut carcinoid tumours. In: Doherty, G.M. and Skogseid, B. (eds.). *Surgical Endocrinology*. Lippincott Williams & Wilkins, Philadelphia, PA, by kind permission).

Somatostatin and its analogues provide symptomatic treatment of the 'carcinoid' syndrome caused by a large volume of liver metastases. These drugs may also have an antiproliferative effect. Surgery to remove liver metastases is possible in approximately 10 per cent of patients. In others, embolisation, chemoembolisation, SRS using radioactively labelled octreotide, chemotherapy, biotherapy and also liver transplantation can be performed.

MULTIPLE ENDOCRINE NEOPLASIAS

Introduction

Multiple endocrine neoplasias (MEN) are inherited syndromes characterised by a combination of benign and malignant tumours in different endocrine glands. There are two main types, type 1 (MEN 1) and type 2 (MEN 2). The mode of inheritance is autosomal dominant in both.

MEN 1 is characterised by the triad of tumours in the anterior pituitary gland, mostly presenting as prolactinomas or non-functioning tumours, hyperplasia of the parathyroids causing primary hyperparathyroidism (pHPT) and pancreaticoduodenal endocrine tumours. The syndrome was first described by Wermer in 1954 and is therefore also called Wermer's syndrome. It is caused by germline mutations in the *menin* gene, located on chromosome 11.

MEN 2 is divided into three subtypes: familial medullary thyroid carcinoma (FMTC), MEN 2a and MEN 2b. Medullary thyroid carcinoma (MTC) plays the key role in all subtypes. MEN 2 is caused by germline mutations in the *RET* proto-oncogene, located on chromosome 10. MEN 2a is characterised by the combination of MTC, pHPT and mostly bilateral pheochromocytomas. MTC combined with pheochromocytoma alone is

called Sipple's syndrome. FMTC is characterised by distinct mutations in *RET* and MTC alone as the clinical manifestation. MEN 2b comprises MTC, pheochromocytoma and characteristic facial and oral mucosal neuromas and intestinal ganglioneuromatosis accompanied by a Marfanoid habitus (Figure 52.25).

The most important difference between MEN 1 and MEN 2, besides the different clinical pictures, is that MEN 2 is characterised by a well-understood genotype–phenotype correlation. This means that depending on the particular mutation in the *RET* proto-oncogene, the phenotypic appearance and the onset of endocrine tumours will be different and can be predicted from the type of mutation. This is not the case in MEN 1 syndrome.

Figure 52.25 Neuromas of the tongue in a patient with multiple endocrine neoplasia type 2b.

Table 52.7 Affected organs in multiple endocrine neoplasia type 1.

Endocrine gland affected	Frequency (%)	Hormone	Clinical syndrome
Parathyroids	90	PTH	pHPT
Pancreas, duodenum (mostly multiple)	50–80		
Gastrinoma		Gastrin	Zollinger–Ellison syndrome
Insulinoma		Insulin	Hypoglycaemia syndrome
Non-functioning tumours		PP	–
VIPoma		VIP	Verner–Morrison syndrome
Glucagonoma		Glucagon	Glucagonoma syndrome
Anterior pituitary gland:	30–60		
Prolactinoma		Prolactin	Galactorrhea
Non-functioning adenoma		–	Non-specific
Other manifestations			
Adrenals	40–50	Mostly non-functioning	
NET in lung, thymus, stomach	3–10	–	–
Lipoma	5–10	–	–

NET, neuroendocrine tumours; pHPT, primary hyperparathyroidism; PP, pancreatic polypeptide; PTH, parathormone; VIP, vasoactive intestinal polypeptide.

Multiple endocrine neoplasia type 1

Epidemiology

The prevalence of the syndrome is estimated to be around 0.04–0.2 cases per 1000 population per year. The penetrance is high with almost 100 per cent of mutation carriers developing the syndrome. The disease is equally distributed between men and women.

Clinical presentation

The clinical presentation depends on the affected organs. Tumours can occur synchronously (Table 52.7). Most of the mutation carriers identified in screening programmes are asymptomatic.

Parathyroids

In total, 90–100 per cent of patients suffering from MEN 1 develop pHPT and it is usually the first manifestation of the disease. MEN 1 pHPT is characterised by multiglandular disease so that all four parathyroids become hyperplastic in the course of the disease. The clinical presentation of MEN 1 pHPT is similar to that of the sporadic disease. Few patients have asymptomatic disease; most common in symptomatic disease is nephrolithiasis. Diagnosis is established by determination of parathyroid hormone (PTH) and calcium in serum and urine.

Endocrine pancreas

PETs occur in around 50–60 per cent of MEN 1 patients. In such patients taking part in screening programmes, 70–90 per cent are found to have non-functioning and functioning PETs. This high rate of detection of PETs is the result of the improvement in diagnostic procedures in the last decade, including EUS. MEN 1 PETs are the most common syndrome-associated cause of death.

They are mostly multiple and often recur after surgery. Although most patients have multiple tumours, one hormone syndrome is usually dominant. The most common functional tumour is gastrinoma followed by insulinoma. VIPomas, glucagonomas and somatostatinomas are extremely rare. Non-functioning tumours can be asymptomatic for many years.

The diagnostic work-up is similar to that for sporadic PETs and includes hormone measurements, e.g. gastrin, insulin, PP, etc., and imaging.

Anterior pituitary gland

Tumours of the anterior pituitary gland are found in 30–60 per cent of patients with MEN 1. These are mostly microadenomas that present as prolactinomas or non-functioning tumours. Most prolactinomas can be treated with medication, thus avoiding operation.

Adrenal tumours and other organ manifestations

Adrenal involvement is common in MEN 1 patients and affects nearly 40–50 per cent of patients. Mostly non-functioning adenomas are found. Very rarely, adrenocortical carcinomas or pheochromocytomas may develop.

Although very rare, manifestations of MEN 1 include NET of the lung, thymus, stomach, duodenum and small bowel. It is important to check for NETs of the thymus, as they are mostly malignant.

Genetic screening

Identification of the MEN 1 (*menin*) gene in 1997 formed the basis for direct mutational analysis of the gene and for family screening. After genetic counselling of the index patient, family members can be screened. Mutation carriers can then be included in screening programmes that make early detection of

John Sipple, born 1930, physician, The State University of New York, New York, NY, USA.

John V Verner, born 1927, an American physician.

AB Morrison, born 1921, an American physician.

endocrine tumours possible. Screening programmes should follow the consensus guidelines published by Brandi *et al.* in 2001. In cases of apparently sporadic endocrine tumours in patients younger than 40 years, genetic testing for MEN 1 is advised.

Operative therapy

Parathyroids

The indications for surgery in MEN 1 pHPT follow the same criteria as in sporadic disease but the choice of procedure is different. As multiglandular disease is present in all cases, resection follows the same rules as in secondary HPT. Therefore, the most common procedures are total parathyroidectomy, including cervical thymectomy or 3½-gland resection, leaving approximately 50 mg of parathyroid tissue behind, and cervical thymectomy. Selective resection of enlarged glands is obsolete because of the high rates of recurrence.

Endocrine pancreas

Indications for surgery and its extent are controversial. Most experts agree that MEN 1 gastrinoma and insulinoma have to be operated on to prevent liver metastases and to control hormonal excess, provided that diffuse liver metastases are not present. MEN 1 gastrinomas are more often located in the duodenum as multiple small tumours than in the pancreas. For gastrinomas located in the duodenum or pancreatic head (gastrinoma triangle, Figure 52.17), pylorus-preserving partial pancreaticoduodenectomy is recommended. In rare cases, the gastrinoma is located in the body or tail of the pancreas. In such cases, distal pancreatectomy with excision of tumours in the pancreatic head is the procedure of choice. In MEN 1 insulinoma the standard operative procedure is distal pancreatectomy with enucleation of tumours in the pancreatic head. Non-functioning PETs are operated on if they reach a size of 1 cm. Careful palpation and IOUS are essential in every pancreatic procedure for MEN 1 PETs.

Anterior pituitary gland

The indications for surgery in tumours of the anterior pituitary gland are the presence of symptomatic non-functional tumours or if medical therapy of prolactinoma fails. Most procedures can be performed through a trans-sphenoidal approach.

Adrenal tumours

Functional adrenal tumours in MEN 1 are rare and have to be operated on. Non-functioning tumours should be resected if they reach a size of 4 cm. Pre- and perioperative management follows the same rules as in sporadic adrenal tumours; therefore, pheochromocytoma has to be ruled out in every patient. In most cases, a laparoscopic or retroperitoneoscopic approach can be used. If there is evidence for a malignant tumour, open surgery is preferred.

Multiple endocrine neoplasia type 2

In most patients with MEN 2a, the disease is caused by mutations of the *RET* proto-oncogene in codon 634. MTC is almost always the first manifestation of the syndrome. If pheochromocytoma and pHPT do not occur, one must suspect the presence of the FMTC subtype. Patients with MEN 2b do not develop pHPT and in 95 per cent of cases mutations in codon 918 of the *RET* proto-oncogene are causative (Table 52.8).

Medullary thyroid carcinoma

MTC is characterised by multicentricity and is often accompanied by C-cell hyperplasia. These characteristics should lead to molecular diagnostic work-up (mutational analysis of the *RET* proto-oncogene) in patients with apparently 'sporadic' MTC. In contrast to sporadic MTC, the diagnosis in families with known mutation of the *RET* gene is mostly made much earlier, possibly as the result of mutational screening and calcitonin measurements. MTC is most aggressive in MEN 2b. It occurs in early childhood, much earlier than in MEN 2a, with lymph node metastases present in the early stages. Preventative surgery is advised around the age of one year.

Primary hyperparathyroidism

pHPT in MEN 2a is less common and has a milder clinical course than MEN 1 pHPT. It occurs in about 20–30 per cent of patients with MEN 2a. Most patients are asymptomatic but all parathyroid glands can become hyperplastic, mostly metachronously. The disease develops after the third decade of life typically.

Pheochromocytoma

The frequency of pheochromocytoma in MEN 2 is around 10–50 per cent and tumours can be bilateral. This can occur synchronously or metachronously. The tumours are almost always benign. Diagnostic work-up includes measurement of urinary catecholamines, abdominal CT or MRI, and ¹³¹I-MIBG scintigraphy (see above).

Operative therapy

Medullary thyroid carcinoma

Operative therapy for MEN 2 MTC in patients detected by genetic screening is a good example of efficient prophylactic surgery, as the likelihood of developing MTC is 100 per cent for most mutations. The mutation carriers can be operated on with no evidence of tumour in the thyroid, protecting them from MTC for the rest of their lives. Different *RET* mutations are associated with early or late onset of the disease. Risk groups have been defined to determine the appropriate age for thyroidectomy (Table 52.9).

Table 52.8 Frequency of diseases in multiple endocrine neoplasia type 2 related to mutation in different codons.

Syndrome	Frequently affected codons in <i>RET</i>	MTC (%)	pHPT (%)	PCC (%)
FMTC	533, 630, 768, 844	90–100	–	–
MEN 2a	609, 634, 790, 804	90–100	20–30	10–50
MEN 2b	883, 918	100	–	10–50

FMTC, familial medullary thyroid cancer; MEN 2a, multiple endocrine neoplasia type 2a; MEN 2b, multiple endocrine neoplasia type 2b; MTC, medullary thyroid cancer; PCC, pheochromocytoma; pHPT, primary hyperparathyroidism; RET, RET proto-oncogene (RET = rearranged during transfection).

Table 52.9 Prophylactic thyroidectomy for medullary thyroid cancer depending on the site of mutation of the *RET* proto-oncogene in multiple endocrine neoplasia type 2 patients with normal calcitonin levels.

	Risk group		
	High	Medium	Low
Codon	883, 918, 922	609, 611, 618, 620, 634	768, 790, 791, 804, 891
Thyroidectomy at age (years)	< 1	6	<20

Phaeochromocytoma

The operative approach is laparoscopy or retroperitoneoscopy. Unilateral or bilateral subtotal resection may be feasible, which retains the healthy part of the gland and prevents postoperative dependence on cortisol and mineralocorticoid supplementation (see above) (Figure 52.26). Further phaeos can develop in the remnants that are left so continued surveillance is required.

Primary hyperparathyroidism

The clinical situation in MEN 2 pHPT is even more difficult than in MEN 1 pHPT because of the association with MTC in MEN 2. During neck surgery for MTC in a eucalcaemic patient, enlarged parathyroid glands should be removed. In cases in which neck surgery has already been performed for MTC, the surgical approach to MEN 2a pHPT should be more tailored to the individual patient. For example, in an older patient after thyroidectomy for MTC with mild asymptomatic hypercalcaemia, localisation procedures and a targeted approach may be appropriate.

Figure 52.26 Bilateral multiple phaeochromocytomas in a patient with multiple endocrine neoplasia type 2a. A, aorta; C, vena cava; white arrows, tumours; black arrow, normal adrenal.

LEARNING OBJECTIVES

To understand:

- Appropriate investigation of breast disease
- Breast anomalies and the complexity of benign breast disease
- The in-depth modern management of breast cancer

COMPARATIVE AND SURGICAL ANATOMY

The protuberant part of the human breast is generally described as overlying the second to the sixth ribs and extending from the lateral border of the sternum to the anterior axillary line. Actually, a thin layer of mammary tissue extends considerably further, from the clavicle above to the seventh or eighth ribs below and from the midline to the edge of the latissimus dorsi posteriorly. This fact is important when performing a mastectomy, the aim of which is to remove the whole breast. The anatomy of the breast is illustrated in Figure 53.1.

The **axillary tail** of the breast is of surgical importance. In some normal subjects it is palpable and, in a few, it can be seen premenstrually or during lactation. A well-developed axillary tail is sometimes mistaken for a mass of enlarged lymph nodes or a lipoma.

The **lobule** is the basic structural unit of the mammary gland. The number and size of the lobules vary enormously: they are most numerous in young women. From 10 to over 100 lobules empty via ductules into a lactiferous duct, of which there are

15–20. Each lactiferous duct is lined with a spiral arrangement of contractile myoepithelial cells and is provided with a terminal ampulla, a reservoir for milk or abnormal discharges.

The **ligaments of Cooper** are hollow conical projections of fibrous tissue filled with breast tissue; the apices of the cones are attached firmly to the superficial fascia and thereby to the skin overlying the breast. These ligaments account for the dimpling of the skin overlying a carcinoma.

The **areola** contains involuntary muscle arranged in concentric rings as well as radially in the subcutaneous tissue. The areolar epithelium contains numerous sweat glands and sebaceous glands, the latter of which enlarge during pregnancy and serve to lubricate the nipple during lactation (Montgomery's tubercles).

The **nipple** is covered by thick skin with corrugations. Near its apex lie the orifices of the lactiferous ducts. The nipple contains smooth muscle fibres arranged concentrically and longitudinally; thus, it is an erectile structure, which points outwards.

The **lymphatics** of the breast drain predominantly into the axillary and internal mammary lymph nodes. The axillary nodes receive approximately 85 per cent of the drainage and are arranged in the following groups:

- **lateral**, along the axillary vein;
- **anterior**, along the lateral thoracic vessels;
- **posterior**, along the subscapular vessels;
- **central**, embedded in fat in the centre of the axilla;
- **interpectoral**, a few nodes lying between the pectoralis major and minor muscles;
- **apical**, which lie above the level of the pectoralis minor tendon in continuity with the lateral nodes and which receive the efferents of all the other groups.

Figure 53.1 Cross-sectional anatomy of the breast.

Sir **Asley Paston Cooper**, 1768–1841, surgeon, Guy's Hospital, London, UK, described these ligaments in 1845. He received a baronetcy and one thousand guineas for successfully removing an infected wen from the head of King George IV at Brighton in 1821. He described scrofulous swellings in the bosoms of young women, most of whom suffered from tuberculous cervical adenitis.

William Fetherston Montgomery, 1797–1859, obstetrician, Dublin, Ireland described these tubercles in 1837. He was instrumental in establishing the Chair of Obstetrics at the Irish College of Physicians.

The apical nodes are also in continuity with the supraclavicular nodes and drain into the subclavian lymph trunk, which enters the great veins directly or via the thoracic duct or jugular trunk. The **sentinel node** is defined as the first lymph node draining the tumour-bearing area of the breast. The importance of the sentinel node is described later.

The internal mammary nodes are fewer in number. They lie along the internal mammary vessels deep to the plane of the costal cartilages, drain the posterior third of the breast and are not routinely dissected although they were at one time biopsied for staging.

INVESTIGATION OF BREAST SYMPTOMS

Although an accurate history and clinical examination are important methods of detecting breast disease, there are a number of investigations that can assist in the diagnosis. Examination precedes palpation and requires careful observation of the patient both with the arms at rest and also elevated to lift the breast. Small lesions may betray their presence by dimpling or minor distortions when the patient moves.

Mammography

Soft tissue radiographs are taken by placing the breast in direct contact with ultrasensitive film and exposing it to

Figure 53.2 Mammogram showing a carcinoma.

low-voltage, high amperage x-rays (Figure 53.2). The dose of radiation is approximately 0.1 cGy and, therefore, mammography is a very safe investigation. The sensitivity of this investigation increases with age as the breast becomes less dense. In total, 5 per cent of breast cancers are missed by population-based mammographic screening programmes; even in retrospect, such carcinomas are not apparent. Thus, a normal mammogram does not exclude the presence of carcinoma. Digital mammography is being introduced, which allows manipulation of the images and computer-aided diagnosis. Tomo-mammography is also being assessed as a more sensitive diagnostic modality.

Ultrasound

Ultrasound is particularly useful in young women with dense breasts in whom mammograms are difficult to interpret, and in distinguishing cysts from solid lesions (Figures 53.3 and 53.4). It can also be used to localise impalpable areas of breast pathology.

Figure 53.3 Ultrasound of the breast showing a cyst (arrow).

Figure 53.4 Ultrasound of the breast showing a carcinoma (arrow).

Gy is short for Gray, the SI unit for the absorbed dose of ionizing radiation.

Louis Harold Gray, 1905–1965, Director, The British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex, UK.

It is not useful as a screening tool and remains operator dependent. Increasingly, ultrasound of the axilla is performed when a cancer is diagnosed with guided percutaneous biopsy of any suspicious glands.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is of increasing interest to breast surgeons in a number of settings:

- It can be useful to distinguish scar from recurrence in women who have had previous breast conservation therapy for cancer (although it is less accurate within nine months of radiotherapy because of abnormal enhancement).
- It is becoming the standard of care when a lobular cancer is diagnosed to assess for multifocality and multicentricity and can be used to assess the extent of DCIS (ductal carcinoma *in situ*).
- It is the best imaging modality for the breasts of women with implants.
- It has proven to be useful as a screening tool in high-risk women (because of family history).
- It is less useful than ultrasound in the management of the axilla in both primary breast cancer and recurrent disease (Figure 53.5).

Although biopsies can be performed with MRI guidance this is complicated because of the configuration of the imaging system. With improved ultrasound equipment, an MRI-detected lesion can often be found on a second-look ultrasound and biopsied using this modality.

Figure 53.5 Magnetic resonance imaging scan of the breasts showing carcinoma of the left breast (arrows). (a) Pre-contrast; (b) post-gadolinium contrast; (c) subtraction image.

Figure 53.6 Corecut biopsy of breast.

Needle biopsy/cytology

Histology can be obtained under local anaesthesia using a spring-loaded core needle biopsy device (Figure 53.6). Cytology is obtained using a 21G or 23G needle and 10-mL syringe with multiple passes through the lump with negative pressure in the syringe. The aspirate is then smeared on to a slide, which is air dried or fixed (Figure 53.7). Fine-needle aspiration cytology (FNAC) is the least invasive technique of obtaining a cell diagnosis and is rapid and very accurate if both operator and cytologist are experienced. However, false negatives do occur, mainly through sampling error, and invasive cancer cannot be distinguished from *in situ* disease. A histological specimen taken by core biopsy allows a definitive preoperative diagnosis, differentiates between duct carcinoma *in situ* and invasive disease and also allows the tumour to be stained for receptor status. This is important before commencing neoadjuvant therapy.

Large-needle biopsy with vacuum systems

The sampling error decreases as the biopsy volume increases and using 8G or 11G needles allows more extensive biopsies to be

Figure 53.7 Fine-needle aspiration cytology (FNAC) showing grade III ductal carcinoma cells.

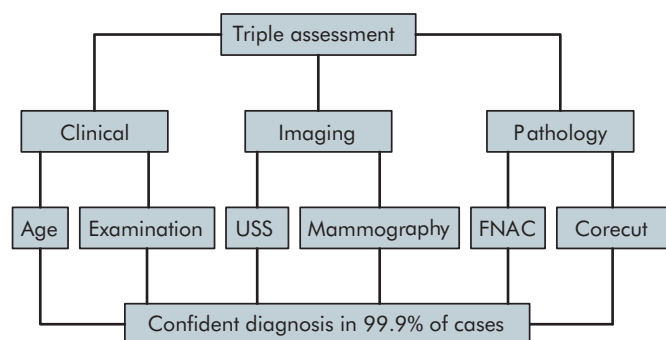

Figure 53.8 Triple assessment of breast symptoms. FNAC, fine-needle aspiration cytology; USS, ultrasound scan.

taken. This is useful in the management of microcalcifications or in the complete excision of benign lesions such as fibroadenomas.

Triple assessment

In any patient who presents with a breast lump or other symptoms suspicious of carcinoma, the diagnosis should be made by a combination of clinical assessment, radiological imaging and a tissue sample taken for either cytological or histological analysis (Figure 53.8), the so-called triple assessment. The positive predictive value (PPV) of this combination should exceed 99.9 per cent.

THE NIPPLE

Absence of the nipple is rare and is usually associated with amazia (congenital absence of the breast).

Supernumerary nipples not uncommonly occur along a line

Figure 53.9 Accessory nipple with congenital retraction of the normal nipple.

Figure 53.10 Recent nipple retraction. (a) Slit-like retraction of duct ectasia with mammary duct fistula. (b) Circumferential retraction with underlying carcinoma.

extending from the anterior fold of the axilla to the fold of the groin (Figure 53.9). This constitutes the milk line of lower mammals. Rarely, there is duplication of the nipple on a normal areola.

Nipple retraction

This may occur at puberty or later in life. Retraction occurring at puberty, also known as **simple nipple inversion**, is of unknown aetiology (benign horizontal inversion). In about 25 per cent of cases it is bilateral. It may cause problems with breastfeeding and infection can occur, especially during lactation, because of retention of secretions. Recent retraction of the nipple may be of considerable pathological significance. A slit-like retraction of the nipple may be caused by duct ectasia and chronic periductal mastitis (Figure 53.10a), but circumferential retraction, with or without an underlying lump, may well indicate an underlying carcinoma (Figure 53.10b).

Treatment

Treatment is usually unnecessary and the condition may spontaneously resolve during pregnancy or lactation.

Simple cosmetic surgery can produce an adequate correction but has the drawback of dividing the underlying ducts. Mechanical suction devices have been used to evert the nipple, with some effect.

Cracked nipple

This may occur during lactation and be the forerunner of acute infective mastitis. If the nipple becomes cracked during lactation, it should be rested for 24–48 hours and the breast should be emptied with a breast pump. Feeding should be resumed as soon as possible.

Papilloma of the nipple

Papilloma of the nipple has the same features as any cutaneous papilloma and should be excised with a tiny disc of skin. Alternatively, the base may be tied with a ligature and the papilloma will spontaneously fall off.

Retention cyst of a gland of Montgomery

These glands, situated in the areola, secrete sebum and if they become blocked a sebaceous cyst forms.

Eczema

Eczema of the nipples is a rare condition and is often bilateral; it is usually associated with eczema elsewhere on the body. It is treated with 0.5 per cent hydrocortisone (not a stronger steroid preparation).

Paget's disease

Paget's disease of the nipple must be distinguished from eczema. The former is caused by malignant cells in the subdermal layer and is usually associated with a carcinoma within the breast. Eczema tends to occur in younger people who have signs of eczema elsewhere (look at the antecubital fossae).

Discharges from the nipple

Discharge can occur from one or more lactiferous ducts. Management depends on the presence of a lump (which should always be given priority in diagnosis and treatment) and the presence of blood in the discharge or discharge from a single duct. Mammography is rarely useful except to exclude an underlying impalpable mass. Cytology may reveal malignant cells but a negative result does not exclude a carcinoma or *in situ* disease.

- A **clear, serous discharge** may be 'physiological' in a parous woman or may be associated with a duct papilloma or mammary dysplasia. Multiduct, multicoloured discharge is physiological and the patient may be reassured.
- A **blood-stained discharge** may be caused by duct ectasia, a duct papilloma or carcinoma. A duct papilloma is usually single and situated in one of the larger lactiferous ducts; it is sometimes associated with a cystic swelling beneath the areola.
- A **black or green discharge** is usually the result of duct ectasia and its complications (Summary box 53.1).

Treatment

Treatment must first be to exclude a carcinoma by occult blood test and cytology. Simple reassurance may then be sufficient but, if the discharge is proving intolerable, an operation to remove the affected duct or ducts can be performed (microdochectomy).

Microdochectomy

It is important not to express the blood before the operation as it may then be difficult to identify the duct in theatre. A lacrimal

Summary box 53.1

Discharges from the nipple (the principal causes are in bold)

Discharge from the surface

- Paget's disease
- Skin diseases (eczema, psoriasis)

probe or length of stiff nylon suture is inserted into the duct from which the discharge is emerging. A tennis racquet incision can be made to encompass the entire duct or a periareolar incision used and the nipple flap dissected to reach the duct. The duct is then excised. A papilloma is nearly always situated within 4–5 cm of the nipple orifice.

Ductoscopy (inspection of the internal structure of the duct system) using microendoscopes is technically feasible but generally disappointing. The affected duct may not be visualised and biopsy systems are currently rudimentary.

Cone excision of the major ducts (after Hadfield) (subareolar resection)

When the duct of origin of nipple bleeding is uncertain or when there is bleeding or discharge from multiple ducts, the entire major duct system can be excised for histological examination without sacrifice of the breast form. A periareolar incision is made and a cone of tissue is removed with its apex just deep to the surface of the nipple and its base on the pectoral fascia. The resulting defect may be obliterated by a series of purse-string sutures although a temporary suction drain will reduce the chance of long-term deformity. It is vital to warn the patient that she will be unable to breastfeed after this and may experience altered nipple sensation.

BENIGN BREAST DISEASE

This is the most common cause of breast problems; up to 30 per cent of women will suffer from a benign breast disorder requiring treatment at some time in their lives. The most common symptoms are pain, lumpiness or a lump. The aim of treatment is to exclude cancer and, once this has been done, to treat any remaining symptoms.

Congenital abnormalities

Amazia

Congenital absence of the breast may occur on one (Figure 53.11) or both sides. It is sometimes associated with absence of the sternal portion of the pectoralis major (Poland's syndrome). It is more common in males.

Polymazia

Accessory breasts (Figure 53.12) have been recorded in the axilla (the most frequent site), groin, buttock and thigh. They have been known to function during lactation.

Mastitis of infants

Mastitis of infants is at least as common in boys as in girls. On the third or fourth day of life, if the breast of an infant is pressed lightly, a drop of colourless fluid can be expressed; a few days later, there is often a slight milky secretion, which disappears during the third week. This is popularly known as 'witch's milk' and is seen only in full-term infants. It is caused by stimulation of the fetal breast by prolactin in response to the drop in maternal oestrogens and is essentially physiological. True mastitis is uncommon and is predominately caused by *Staphylococcus aureus*.

Diffuse hypertrophy

Diffuse hypertrophy of the breasts occurs sporadically in otherwise healthy girls at puberty (benign virginal hypertrophy) and, much less often, during the first pregnancy. The breasts attain enormous dimensions and may reach the knees when the patient is sitting. The condition is rarely unilateral. This tremendous

Figure 53.11 Congenital absence of the right breast.

Figure 53.12 Bilateral accessory breasts.

overgrowth is apparently caused by an alteration in the normal sensitivity of the breast to oestrogenic hormones and some success in treating it with anti-oestrogens has been reported. Treatment is otherwise by reduction mammoplasty.

Injuries of the breast

Haematoma

Haematoma, particularly a resolving haematoma, gives rise to a lump, which, in the absence of overlying bruising, is difficult to diagnose correctly unless it is biopsied.

Traumatic fat necrosis

Traumatic fat necrosis may be acute or chronic and usually occurs in stout, middle-aged women. Following a blow, or even indirect violence (e.g. contraction of the pectoralis major), a lump, often painless, appears. This may mimic a carcinoma, even displaying skin tethering and nipple retraction, and biopsy is required for diagnosis. A history of trauma is not diagnostic as this may merely have drawn the patient's attention to a pre-existing lump. A seatbelt may transect the breast with a sudden deceleration injury, as in a road traffic accident.

Acute and subacute inflammations of the breast

Bacterial mastitis

Bacterial mastitis is the most common variety of mastitis and is associated with lactation in the majority of cases.

Aetiology

Lactational mastitis is seen far less frequently than in former years. Most cases are caused by *S. aureus* and, if hospital acquired, are likely to be penicillin resistant. The intermediary is usually the infant; after the second day of life, 50 per cent of infants harbour staphylococci in the nasopharynx.

Although ascending infection from a sore and cracked nipple may initiate the mastitis, in many cases the lactiferous ducts will first become blocked by epithelial debris leading to stasis; this theory is supported by the relatively high incidence of mastitis in women with a retracted nipple. Once within the ampulla of the duct, staphylococci cause clotting of milk and, within this clot, organisms multiply.

Clinical features

The affected breast, or more usually a segment of it, presents the classical signs of acute inflammation. Early on this is a generalised cellulitis but later an abscess will form.

Treatment

During the cellulitic stage the patient should be treated with an appropriate antibiotic, for example flucloxacillin or co-amoxiclav. Feeding from the affected side may continue if the patient can manage. Support of the breast, local heat and analgesia will help to relieve pain.

If an antibiotic is used in the presence of undrained pus, an 'antibioma' may form. This is a large, sterile, brawny oedematous swelling that takes many weeks to resolve.

It used to be recommended that the breast should be incised and drained if the infection did not resolve within 48 hours or if after being emptied of milk there was an area of tense induration or other evidence of an underlying abscess. This advice has been replaced with the recommendation that repeated aspirations under antibiotic cover (if necessary using ultrasound for localisation) be performed. This often allows resolution without the need for an incision scar and will also allow the patient to carry on breastfeeding.

The presence of pus can be confirmed with needle aspiration and the pus sent for bacteriological culture. In contrast to the majority of localised infections, fluctuation is a late sign. Usually, the area of induration is sector-shaped and, in early cases, about

one-quarter of the breast is involved (Figure 53.13); in many late cases the area is more extensive (Figure 53.14). When in doubt, an ultrasound scan may clearly define an area suitable for drainage.

Operative drainage of a breast abscess

This is less commonly needed as prompt commencement of antibiotics and repeated aspiration is usually successful. Incision of a lactational abscess is necessary if there is marked skin thinning and can usually be performed under local anaesthesia if an analgesic cream such as EMLA (lidocaine) is applied 30 minutes before surgery.

The usual incision is sited in a radial direction over the affected segment, although if a circumareolar incision will allow adequate access to the affected area this is preferred because it gives a better cosmetic result. The incision passes through the skin and the superficial fascia. A long artery forceps is then inserted into the abscess cavity. Every part of the abscess is palpated against the point of the artery forceps and its jaws are opened. All loculi that can be felt are entered.

Finally, the artery forceps having been withdrawn, a finger is introduced and any remaining septa are disrupted. The wound may then be lightly packed with ribbon gauze or a drain inserted to allow dependent drainage.

Chronic intramammary abscess

A chronic intramammary abscess, which may follow inadequate drainage or injudicious antibiotic treatment, is often a very difficult condition to diagnose. When encapsulated within a thick wall of fibrous tissue the condition cannot be distinguished from a carcinoma without the histological evidence from a biopsy.

Tuberculosis of the breast

Tuberculosis of the breast, which is comparatively rare, is usually associated with active pulmonary tuberculosis or tuberculous cervical adenitis.

Tuberculosis of the breast (Figure 53.15) occurs more often in parous women and usually presents with multiple chronic abscesses and sinuses and a typical bluish, attenuated appearance

Figure 53.13 Intramammary breast abscess.

Figure 53.14 Large breast abscess.

Figure 53.15 Tuberculosis of the breast with secondary suppurating axillary lymph nodes (courtesy of Professor AK Toufeeq, Lahore, Pakistan).

Figure 53.16 Mondor's disease of the right breast.

of the surrounding skin. The diagnosis rests on bacteriological and histological examination. Treatment is with anti-tuberculous chemotherapy. Healing is usual, although often delayed, and mastectomy should be restricted to patients with persistent residual infection.

Actinomycosis

Actinomycosis of the breast is rarer still. The lesions present the essential characteristics of faciocervical actinomycosis.

Mondor's disease

Mondor's disease is thrombophlebitis of the superficial veins of the breast and anterior chest wall (Figure 53.16), although it has also been encountered in the arm.

In the absence of injury or infection, the cause of thrombophlebitis (like that of spontaneous thrombophlebitis in other

Figure 53.17 Subareolar abscess in duct ectasia.

Figure 53.18 Mammary fistula originating in a chronic subareolar abscess.

sites) is obscure. The pathognomonic feature is a thrombosed subcutaneous cord, usually attached to the skin. When the skin over the breast is stretched by raising the arm, a narrow, shallow subcutaneous groove alongside the cord becomes apparent. The differential diagnosis is lymphatic permeation from an occult carcinoma of the breast. The only treatment required is restricted arm movements and, in any case, the condition subsides within a few months without recurrence, complications or deformity. There are case reports of Mondor's disease being associated with subsequent development of malignancy although this has been unsubstantiated by others and is thought to be coincidental.

Duct ectasia/periductal mastitis

Pathology

This is a dilatation of the breast ducts, which is often associated with periductal inflammation. The pathogenesis is obscure and almost certainly not uniform in all cases, although the disease is much more common in smokers.

The classical description of the pathogenesis of duct ectasia asserts that the first stage in the disorder is a dilatation in one or more of the larger lactiferous ducts, which fill with a stagnant brown or green secretion. This may discharge. These fluids then set up an irritant reaction in surrounding tissue leading to periductal mastitis or even abscess and fistula formation (Figures 53.17 and 53.18). In some cases, a chronic indurated mass forms beneath the areola, which mimics a carcinoma. Fibrosis eventually develops, which may cause slit-like nipple retraction.

An alternative theory suggests that periductal inflammation is the primary condition and, indeed, anaerobic bacterial infection is found in some cases. A marked association between recurrent periductal inflammation and smoking has been demonstrated. This was thought by some to indicate that arteriopathy is a contributing factor in its aetiology although others believe that smoking increases the virulence of the commensal bacteria. It is certainly clear that cessation of smoking increases the chance of a long-term cure.

Clinical features

Nipple discharge (of any colour), a subareolar mass, abscess, mammary duct fistula and/or nipple retraction are the most common symptoms.

Treatment

In the case of a mass or nipple retraction, a carcinoma must be excluded by obtaining a mammogram and negative cytology or histology. If any suspicion remains the mass should be excised.

Antibiotic therapy may be tried, the most appropriate agents being co-amoxiclav or flucloxacillin and metronidazole. However, surgery is often the only option likely to bring about cure of this notoriously difficult condition; this consists of excision of all of the major ducts (Hadfield's operation). It is particularly important to shave the back of the nipple to ensure that all terminal ducts are removed. Failure to do so will lead to recurrence.

Aberrations of normal development and involution

Nomenclature

The nomenclature of benign breast disease is confusing. This is because over the last century a variety of clinicians and pathologists have chosen to describe a mixture of physiological changes and disease processes according to a variety of clinical, pathological and aetiological terminology. As well as leading to confusion, patients were often unduly alarmed or overtreated by ascribing a pathological name to a variant of physiological development. To address this confusion, a concept (aberrations of normal development and involution (ANDI)) has been developed and described by the Cardiff Breast Clinic.

Aetiology

The breast is a dynamic structure that undergoes changes throughout a woman's reproductive life and, superimposed upon this, cyclical changes throughout the menstrual cycle. This is illustrated in Figure 53.19. The pathogenesis of ANDI involves disturbances in the breast physiology extending from a perturbation of normality to well-defined disease processes. There is often little correlation between the histological appearance of the breast tissue and the symptoms.

Pathology

The disease consists essentially of four features that may vary in extent and degree in any one breast:

- 1 **Cyst formation.** Cysts are almost inevitable and very variable in size.
- 2 **Fibrosis.** Fat and elastic tissues disappear and are replaced with dense white fibrous trabeculae. The interstitial tissue is infiltrated with chronic inflammatory cells.
- 3 **Hyperplasia** of epithelium in the lining of the ducts and acini may occur, with or without atypia.
- 4 **Papillomatosis.** The epithelial hyperplasia may be so extensive that it results in papillomatous overgrowth within the ducts.

Clinical features

The symptoms of ANDI are many as the term is used to encompass a wide range of benign conditions, but often include an area of lumpiness (seldom discrete) and/or breast pain (mastalgia).

- A benign discrete lump in the breast is commonly a cyst or fibroadenoma. True lipomas occur rarely.
- Lumpiness may be bilateral, commonly in the upper outer quadrant or, less commonly, confined to one quadrant of one

Figure 53.19 Normal breast changes throughout life. UK National Health Service Breast Screening Programme data.

breast. The changes may be cyclical, with an increase in both lumpiness and often tenderness before a menstrual period.

- Non-cyclical mastalgia is more common in perimenopausal than postmenopausal women. It may be associated with ANDI or with periductal mastitis. It should be distinguished from referred pain, for example a musculoskeletal disorder. 'Breast' pain in postmenopausal women not taking hormone replacement therapy (HRT) is usually derived from the chest wall, back or neck.

About 5 per cent of breast cancers exhibit pain at presentation, but rarely as the sole presenting feature.

Treatment of lumpy breasts

If the clinician is confident that he or she is not dealing with a discrete abnormality (and clinical confidence is supported by mammography and/or ultrasound scanning if appropriate), then initially the woman can be offered firm reassurance. It is perhaps worthwhile reviewing the patient at a different point in the menstrual cycle, for example 6 weeks after the initial visit, and often the clinical signs will have resolved by that time. There is a tendency for women with lumpy breasts to be rendered unnecessarily anxious and to be submitted to multiple random biopsies because the clinician lacks the courage of his or her convictions. Rapid referral into the secondary health-care system often means patients are assessed without an intervening menstrual cycle and this may lead to additional concerns.

Treatment of mastalgia

Pronounced cyclical mastalgia may become a significant clinical problem if the pain and tenderness interfere with the woman's life, disturb her sleep and impair sexual activity. Initially, firm reassurance that the symptoms are not associated with cancer will help the majority of women. Acknowledgement that this is a real symptom, a non-dismissive attitude and an explanation of the aetiology are all helpful in managing this condition.

In the first instance, an appropriately fitting and supportive bra should be worn throughout the day and a soft bra (such as a sports bra) worn at night. Avoiding caffeine drinks is said to help, although the author remains unconvinced.

A patient symptom diary will help her to chart the pattern of pain throughout the month and thus determine whether this is cyclical mastalgia. This allows the majority of patients to adjust to the concept of a cyclical nature of their problem

Table 53.1 Treatment of breast pain.

Exclude cancer	
Reassure	Use pain chart if unsure if cyclical or non-cyclical. Also allows time for reassurance to become active!
Adequate support	Firm bra during the day and a softer bra at night
Exclude caffeine	Works for some although not very efficacious in author's practice
Consider medication	
Evening primrose oil (GLA)	Better effect in women over 40 years old than in younger women
Danazol, 100 mg three times a day	Start at 100 mg per day and increase (seldom used these days)
Tamoxifen	Not licensed for this indication but occasionally very helpful

but, if reassurance is inadequate, then a planned escalation of treatment (Table 53.1) could be advised. Oil of evening primrose, in adequate doses given over three months, will help more than half of these women. It appears to achieve higher response rates in those over 40 years of age rather than younger women. For those with intractable symptoms, an anti-gonadotrophin, such as danazol, or a prolactin inhibitor, such as bromocriptine, may be tried. Very rarely, it is necessary to prescribe an anti-oestrogen, for example tamoxifen, or a luteinising hormone-releasing hormone (LHRH) agonist to deprive the breast epithelium of oestrogenic drive. Ablative surgery should never be contemplated for breast pain and any patient seeking this treatment should be referred to a psychiatrist.

For non-cyclical mastalgia it is important to exclude extramammary causes such as chest wall pain. This is common in postmenopausal women who are not on HRT and the neck and shoulders are common sights of referred pain. It is seldom necessary these days to carry out a biopsy on a very localised tender area that might be harbouring a subclinical cancer as imaging is so much better. Treatment may be with non-steroidal analgesics or by injection with local anaesthetic on a 'trigger spot'.

Breast cysts

These occur most commonly in the last decade of reproductive life as a result of a non-integrated involution of stroma and epithelium. They are often multiple, may be bilateral and can mimic malignancy. Diagnosis can be confirmed by aspiration and/or ultrasound. They typically present suddenly and cause great alarm; prompt diagnosis and drainage provides immediate relief.

Treatment

A solitary cyst or small collection of cysts can be aspirated. If they resolve completely, and if the fluid is not blood-stained, no further treatment is required. However, 30 per cent will recur and require reaspiration. Cytological examination of cyst fluid is no longer practised routinely. If there is a residual lump or if the fluid is blood-stained, a core biopsy or local excision for histological diagnosis is advisable, which is also the case if the cyst reforms repeatedly. This will exclude cystadenocarcinoma, which is more common in elderly women.

Galactocoele

Galactocoele, which is rare, usually presents as a solitary, subareolar cyst and always dates from lactation. It contains milk and in long-standing cases its walls tend to calcify.

Fibroadenoma

These usually arise in the fully developed breast between the ages of 15 and 25 years, although occasionally they occur in much older women. They arise from hyperplasia of a single lobule and usually grow up to 2–3 cm in size. They are surrounded by a well-marked capsule and can thus be enucleated through a cosmetically appropriate incision. A fibroadenoma does not require excision unless associated with suspicious cytology, it becomes very large or the patient expressly desires the lump to be removed.

Giant fibroadenomas occasionally occur during puberty. They are over 5 cm in diameter and are often rapidly growing but, in other respects, are similar to smaller fibroadenomas and can be enucleated through a submammary incision. They are more common in the Afro-Caribbean population.

Phyllodes tumour

These benign tumours, previously sometimes known as serocystic disease of Brodie or cystosarcoma phyllodes, usually occur in women over the age of 40 years but can appear in younger women. They present as a large, sometimes massive, tumour with an unevenly bosselated surface. Occasionally, ulceration of overlying skin occurs because of pressure necrosis. Despite their size they remain mobile on the chest wall. Histologically, there is a wide variation in their appearance, with some of low malignant potential resembling a fibroadenoma and others having a higher mitotic index, which are histologically worrying. The latter may recur locally but, despite the name of cystosarcoma phyllodes, they are rarely cystic and only very rarely develop features of a sarcomatous tumour. These may metastasise via the bloodstream.

Treatment

Treatment for the benign type is enucleation in young women or wide local excision. Massive tumours, recurrent tumours and those of the malignant type will require mastectomy (Summary box 53.2).

When the diagnosis of carcinoma is in doubt

There will always be cases when the clinician cannot be sure whether a particular lump in the breast is an area of mammary dysplasia, a benign tumour or an early carcinoma.

If there is doubt on clinical, cytological or radiological examination, it is essential to obtain a tissue diagnosis. This is often

Sir Benjamin Collins Brodie, 1783–1862, surgeon, St George's Hospital, London, UK, described serocystic disease of the breast in 1840.
Phylloides – from the Greek = leaflike.
Alexander Tietze, 1864–1927, Professor of Surgery, Breslau, Germany (now Wroclaw, Poland), described this condition in 1921.

- Pregnancy-related
 - Galactocoele
 - Puerperal abscess

possible by needle biopsy. In the event of a negative result, open biopsy of the mass or large-gauge vacuum biopsy is necessary. Because of the possibility of reporting errors and because the histology is likely to be more difficult (if a diagnosis has not already been made), the author suggests that frozen-section reporting should be used rarely and certainly should not form the basis for a decision to undertake a mastectomy. Table 53.2 gives an algorithm for investigating any breast lump.

Risk of malignancy developing in association with benign breast pathology

The relative risks of malignancy developing according to different histological features found at biopsy are illustrated in Table 53.3.

These were elucidated 30 years ago but remain pertinent and a recent single-centre review reinforces the conclusion that the histological classification of the benign lesion in combination with a family history of breast cancer are important predictors of risk.

CARCINOMA OF THE BREAST

Breast cancer is the most common cause of death in middle-aged women in Western countries. In 2010, approximately one and three-quarter million new cases were diagnosed worldwide. In England and Wales, 1 in 12 women will develop the disease during their lifetime. The incidence is expected to continue rising as the population ages although more slowly than previously thought as the use of HRT has reduced in the USA and UK.

Aetiological factors

Geographical

Carcinoma of the breast occurs commonly in the Western world, accounting for 3–5 per cent of all deaths in women. In developing countries it accounts for 1–3 per cent of deaths.

Age

Carcinoma of the breast is extremely rare below the age of 20 years but, thereafter, the incidence steadily rises so that by the age of 90 years nearly 20 per cent of women are affected.

Gender

Less than 0.5 per cent of patients with breast cancer are male.

Genetic

It occurs more commonly in women with a family history of breast cancer than in the general population. Breast cancer related to a specific mutation accounts for about 5 per cent of breast cancers yet has far-reaching repercussions in terms of counselling and tumour prevention in these women. This will be discussed more fully in a subsequent section (see under Familial breast cancer).

Diet

Because breast cancer so commonly affects women in the 'developed' world, dietary factors may play a part in its causation. There is some evidence that there is a link with diets low in phyto-oestrogens. A high intake of alcohol is associated with an increased risk of developing breast cancer.

Endocrine

Breast cancer is more common in nulliparous women and breastfeeding in particular appears to be protective. Also protective is having a first child at an early age, especially if associated with late menarche and early menopause. It is known that in postmenopausal women, breast cancer is more common in the obese. This is thought to be because of an increased conversion of steroid hormones to oestradiol in the body fat. Recent studies have clarified the role of exogenous hormones, in particular the oral contraceptive pill and HRT, in the development of breast cancer. For most women the benefits of these treatments will far outweigh the small putative risk; however, long-term exposure to the combined preparation of HRT does significantly increase the risk of developing breast cancer. The recent fall in use of HRT in USA and UK has seen a reduction in the incidence of breast cancer in the 50- to 60-year-old cohort.

Previous radiation

This was considered to be of historical interest, as the majority of women exposed to the atomic bombs at Hiroshima and

Nagasaki have now died. It is, however, a real problem in women who have been treated with mantle radiotherapy as part of the management of Hodgkin’s disease, in which significant doses of radiation to the breast are received. The risk appears about a decade after treatment and is higher if radiotherapy occurred during breast development. A surveillance programme has been organised in the UK with MRI and mammographic screening.

Pathology

Breast cancer may arise from the epithelium of the duct system anywhere from the nipple end of the major lactiferous ducts to the terminal duct unit, which is in the breast lobule. The disease may be entirely *in situ*, an increasingly common finding with the advent of breast cancer screening, or may be invasive cancer. The degree of differentiation of the tumour is usually described using three grades: well differentiated, moderately differentiated or poorly differentiated. Commonly, a numerical grading system based on the scoring of three individual factors (nuclear pleomorphism, tubule formation and mitotic rate) is used, with grade III cancers roughly equating to the poorly differentiated group. Previously, descriptive terms were used to classify breast cancer (‘scirrhous’, meaning woody, or ‘medullary’, meaning brain-like). More recently, histological descriptions have been used. These have been shown to have clinical correlations in the way that the tumour behaves and are likely to be used for the near future. However, with the increasing application of molecular markers there will be a change in the way that breast cancers are classified and it is likely that much more information about an individual tumour will be routinely reported, such as its likelihood of metastasis and to which therapeutic agents it will be susceptible. Gene array analysis of breast cancers has identified five subtypes. Some of these correlate with known markers such as oestrogen receptor status. There are specific gene signatures

that are said to correlate with response to chemotherapy or poor prognosis; trials based upon these differences are planned. A commercial test is now available to patients with oestrogen-positive tumours to assess their risk of recurrence. This is based on analysis of 21 genes and may allow selection of patients in whom more aggressive therapy is indicated.

Current nomenclature

Ductal carcinoma is the most common variant with **lobular carcinoma** occurring in up to 15 per cent of cases. There are subtypes of lobular cancer including the classical type, which carries a better prognosis than the pleomorphic type. Occasionally, the picture may be mixed with both ductal and lobular features. There are different patterns of spread depending on histological type. If there is doubt whether a tumour is predominantly lobular in type, immunohistochemical analysis using the e-cadherin antibody, which reacts positively in lobular cancer, will help in diagnosis. Rarer histological variants, usually carrying a better prognosis, include **colloid or mucinous carcinoma**, whose cells produce abundant mucin, **medullary carcinoma**, with solid sheets of large cells often associated with a marked lymphocytic reaction, and **tubular carcinoma**. Invasive lobular carcinoma is commonly multifocal and/or bilateral, hence the increasing use of MRI for assessment. Cases detected via the screening programme are often smaller and better differentiated than those presenting to the symptomatic service and are of a special type. **Inflammatory carcinoma** is a fortunately rare, highly aggressive cancer that presents as a painful, swollen breast, which is warm with cutaneous oedema. This is the result of blockage of the subdermal lymphatics with carcinoma cells. Inflammatory cancer usually involves at least one-third of the breast and may mimic a breast abscess. A biopsy will confirm the diagnosis and

show undifferentiated carcinoma cells. It used to be rapidly fatal but with aggressive chemotherapy and radiotherapy and with salvage surgery the prognosis has improved considerably.

In situ carcinoma is preinvasive cancer that has not breached the epithelial basement membrane. This was previously a rare, usually asymptomatic, finding in breast biopsy specimens but is becoming increasingly common because of the advent of mammographic screening; it now accounts for over 20 per cent of cancers detected by screening in the UK. *In situ carcinoma* may be ductal (DCIS) or lobular (LCIS), the latter often being multifocal and bilateral. Both are markers for the later development of invasive cancer, which will develop in at least 20 per cent of patients. Although mastectomy is curative, this constitutes overtreatment in many cases. The best treatment for *in situ carcinoma* is the subject of a number of ongoing clinical trials. DCIS may be classified using the Van Nuys system, which combines the patient's age, type of DCIS and presence of microcalcification, extent of resection margin and size of disease. Patients with a high score benefit from radiotherapy after excision, whereas those of low grade, whose tumour is completely excised, need no further treatment.

Staining for oestrogen and progesterone receptors is now considered routine, as their presence will indicate the use of adjuvant hormonal therapy with tamoxifen or an aromatase inhibitor (Figure 53.20). Tumours are also stained for c-erbB2 (also known as HER-2/neu) (a growth factor receptor) as patients who are positive can be treated with the monoclonal antibody trastuzumab (Herceptin®), either in the adjuvant or relapse setting.

The pathologist is an important member of the breast cancer team and will increasingly help decide which adjuvant therapies will be appropriate.

Paget's disease of the nipple

Paget's disease of the nipple (Figure 53.21a and b) is a superficial manifestation of an underlying breast carcinoma. It presents as an eczema-like condition of the nipple and areola, which persists despite local treatment. The nipple is eroded slowly and eventually disappears. If left, the underlying carcinoma will sooner or later become clinically evident. Nipple eczema should

Figure 53.20 Immunohistochemical staining for oestrogen receptors.

Figure 53.21 (a) Paget's disease of the nipple. (b) Histological appearance of Paget's disease.

be biopsied if there is any doubt about its cause. Microscopically, Paget's disease is characterised by the presence of large, ovoid cells with abundant, clear, pale-staining cytoplasm in the Malpighian layer of the epidermis.

The spread of breast cancer

Local spread

The tumour increases in size and invades other portions of the breast. It tends to involve the skin and to penetrate the pectoral muscles and even the chest wall if diagnosed late.

Lymphatic metastasis

Lymphatic metastasis occurs primarily to the axillary and the internal mammary lymph nodes. Tumours in the posterior one-third of the breast are more likely to drain to the internal mammary nodes. The involvement of lymph nodes has both biological and chronological significance. It represents not only an evolutionary event in the spread of the carcinoma but is also a marker for the metastatic potential of that tumour. Involvement of supraclavicular nodes and of any contralateral lymph nodes represents advanced disease.

Spread by the bloodstream

It is by this route that skeletal metastases occur, although the initial spread may be via the lymphatic system. In order of

frequency, the lumbar vertebrae, femur, thoracic vertebrae, rib and skull are affected and these deposits are generally osteolytic. Metastases may also commonly occur in the liver, lungs and brain and, occasionally, the adrenal glands and ovaries; they have, in fact, been described in most body sites.

Clinical presentation

Although any portion of the breast, including the axillary tail, may be involved, breast cancer is found most frequently in the upper outer quadrant (Figures 53.22 and 53.23). Most breast cancers will present as a hard lump, which may be associated with indrawing of the nipple. As the disease advances locally there may be skin involvement with peau d'orange (Figure 53.24) or frank ulceration and fixation to the chest wall (Figure 53.25). This is described as cancer-en-cuirasse when the disease progresses around the chest wall. About 5 per cent of breast cancers in the UK will present with either locally advanced disease or symptoms of metastatic disease. This figure is much higher in the developing world. These patients must then undergo a staging evaluation so that the full extent of their disease can be ascertained. This will include a careful clinical examination,

Figure 53.22 Invasive carcinoma of the right breast. Note the shrinking and elevation of the breast with nipple retraction.

chest radiograph, computed tomography (CT) of the chest and abdomen and an isotope bone scan (Figure 53.26). This is important for both prognosis and treatment; a patient with widespread visceral metastases may obtain an increased length and quality of survival from systemic hormone therapy or chemotherapy but is unlikely to benefit from surgery as she will die from her metastases before local disease becomes a problem. In contrast, patients with relatively small tumours (<2 cm in diameter) confined to the breast and ipsilateral lymph nodes rarely need staging beyond a good clinical examination as the pick-up rate for distant metastases is so low. Currently, a chest radiograph, full blood count and liver function tests are all that are recommended for screening of patients with early-stage breast cancer.

Staging of breast cancer

Classical staging of breast cancer by means of the TNM (tumour–node–metastasis) or UICC (Union Internationale Contre le Cancer) criteria is used less often as we gain more knowledge of the biological variables that affect prognosis. It is becoming increasingly clear that it is these factors (discussed in more detail below) rather than anatomical mapping that influence outcome and treatment. Perhaps a more pragmatic approach would be to classify patients according to the treatment that they require (Table 53.4). Treatment recommendations are summarised in consensus statements such as those from the American Society of Clinical Oncology (ASCO) and the St Gallen Conference.

Prognosis of breast cancer

The best indicators of likely prognosis in breast cancer remain tumour size, grade and lymph node status; however, it is realised that some large tumours will remain confined to the breast

Figure 53.23 The relationship of carcinoma of the breast to the quadrants of the breast.

Table 53.4 A pragmatic classification of breast cancer.

Group	Approximate 5-year survival rate (%)	Example	Treatment
'Very low-risk' primary breast cancer	>90	Screen-detected DCIS, tubular or special types	Local
'Low-risk' primary breast cancer	70–90	Node negative with favourable histology	Locoregional with/without systemic
'High-risk' primary breast cancer	<70	Node positive or unfavourable histology	Locoregional with systemic
Locally advanced	<30	Large primary or inflammatory	Primary systemic
Metastatic	–	–	Primary systemic

DCIS, duct carcinoma *in situ*.

for decades whereas some very small tumours are incurable at diagnosis. Hence, the prognosis of a cancer depends not on its chronological age but on its invasive and metastatic potential. In an attempt to define which tumours will behave aggressively, and thus require early systemic treatment, a host of prognostic factors have been described. These include the histological grade of the tumour, hormone receptor status, measures of tumour proliferation such as S-phase fraction, growth factor analysis and oncogene or oncogene product measurements. Many others are under investigation but have proved of little practical value in patient management. Prognostic indices (such as the Nottingham prognostic index) have combined these factors to allow subdivision of patients into discrete prognostic groups. More recently, computer-aided programs (adjuvant online; www.adjuvantonline.com or in the UK Predict; www.predict.nhs.uk) have been developed, which incorporate the putative benefits of treatment allowing oncologist and patient to visualise the benefits of therapy.

Treatment of cancer of the breast

The two basic principles of treatment are to reduce the chance of local recurrence and the risk of metastatic spread. Treatment of early breast cancer will usually involve surgery with or without radiotherapy. Systemic therapy such as chemotherapy or hormone therapy is added if there are adverse prognostic factors such as lymph node involvement, indicating a high likelihood

Figure 53.25 Ulcerated carcinoma of the right breast.

Figure 53.26 Skeletal isotope bone scan showing multiple 'hot-spots' due to metastases.

of metastatic relapse. At the other end of the spectrum, locally advanced or metastatic disease is usually treated by systemic therapy to palliate symptoms, with surgery playing a much smaller role. An algorithm for the management of breast cancer is shown in Summary box 53.3.

The multidisciplinary team approach

As in all branches of medicine, good doctor–patient communication plays a vital role in helping to alleviate patient anxiety. Participation of the patient in treatment decisions is of particular importance in breast cancer when there may be uncertainty as

Summary box 53.3**Algorithm for management of operable breast cancer**

- Achieve local control
- Appropriate surgery
 - Wide local excision (clear margins) and radiotherapy, or
 - Mastectomy \pm radiotherapy (offer reconstruction – immediate or delayed)
 - Combined with axillary procedure (see text)
 - Await final pathology and receptor measurements
 - Use risk assessment tool; stage if appropriate
- Treat risk of systemic disease
 - Offer chemotherapy if prognostic factors poor; include Herceptin if Her-2 positive
 - Radiotherapy as decided above
 - Hormone therapy if oestrogen receptor or progesterone receptor positive

to the best therapeutic option and the desire to treat the patient within the protocol of a controlled clinical trial. As part of the preoperative and postoperative management of the patient it is often useful to employ the skills of a trained breast counsellor and also to have available advice on breast prostheses, psychological support and physiotherapy, when appropriate.

In many specialist centres the care of breast cancer patients is undertaken as a joint venture between the surgeon, medical oncologist, radiotherapist and allied health professionals such as the clinical nurse specialist. This has been shown to be good for the patient, to lead to higher trial entry and to improve the mental health of the professionals in the breast team. There are published guidelines for the optimal management of patients with breast cancer, such as SIGN 84 (Scottish Intercollegiate Guidelines Network).

Local treatment of early breast cancer

Local control is achieved through surgery and/or radiotherapy (Summary box 53.4).

Summary box 53.4**Treatment of early breast cancer****The aims of treatment are:**

- 'Cure': likely in some patients but late recurrence is possible
- Control of local disease in the breast and axilla
- Conservation of local form and function
- Prevention or delay of the occurrence of distant metastases

Surgery

Surgery still has a central role to play in the management of breast cancer but there has been a gradual shift towards more conservative techniques, backed up by clinical trials that have shown equal efficacy between mastectomy and local excision followed by radiotherapy.

It was initially hoped that avoiding mastectomy would help to alleviate the considerable psychological morbidity associated

with breast cancer, but recent studies have shown that over 30 per cent of women develop significant anxiety and depression following both radical and conservative surgery. After mastectomy women tend to worry about the effect of the operation on their appearance and relationships, whereas after conservative surgery they may remain fearful of a recurrence.

Mastectomy is indicated for large tumours (in relation to the size of the breast), central tumours beneath or involving the nipple, multifocal disease, local recurrence or patient preference. The radical Halsted mastectomy, which included excision of the breast, axillary lymph nodes and pectoralis major and minor muscles, is no longer indicated as it causes excessive morbidity with no survival benefit. The modified radical (Patey) mastectomy is more commonly performed and is thus described below. Simple mastectomy involves removal of only the breast with no dissection of the axilla, except for the region of the axillary tail of the breast, which usually has attached to it a few nodes low in the anterior group.

Patey mastectomy

The breast and associated structures are dissected *en bloc* (Figure 53.27) and the excised mass is composed of:

- the whole breast;
- a large portion of skin, the centre of which overlies the tumour but which always includes the nipple;
- all of the fat, fascia and lymph nodes of the axilla.

The pectoralis minor muscle is either divided or retracted to gain access to the upper two-thirds of the axilla. The axillary vein and nerves to the serratus anterior and latissimus dorsi (the thoracodorsal trunk) should be preserved. The intercostal brachial nerves are usually divided in this operation and the patient should be warned about sensation changes postoperatively.

The wound is drained using a wide-bore suction tube. Early mobilisation of the arm is encouraged and physiotherapy helps normal function to return very quickly; most patients are able to resume light work or housework within a few weeks.

Conservative breast cancer surgery

This is aimed at removing the tumour plus a rim of at least 1 cm of normal breast tissue. This is commonly referred to as a wide local excision. The term lumpectomy should be reserved for an operation in which a benign tumour is excised and in which a large amount of normal breast tissue is not resected. A quadrantectomy involves removing the entire segment of the breast that contains the tumour. Both of these operations are usually combined with axillary surgery, usually via a separate incision in the axilla. There are various options that can be used to deal with the axilla, including sentinel node biopsy, sampling, removal of the nodes behind and lateral to the pectoralis minor (level II) or a full axillary dissection (level III).

There is a somewhat higher rate of local recurrence following conservative surgery, even if combined with radiotherapy, but the long-term outlook in terms of survival is unchanged. Local recurrence is more common in younger women and in those with high-grade tumours and involved resection margins. Patients whose margins are involved should have a further local excision (or a mastectomy) before going on to radiotherapy. Excision of a breast cancer without radiotherapy leads to an unacceptable local recurrence rate.

The role of axillary surgery is to stage the patient and to treat

the axilla. The presence of metastatic disease within the axillary lymph nodes remains the best single marker for prognosis; however, treatment of the axilla does not affect long-term survival, suggesting that the axillary nodes act not as a 'reservoir' for disease but as a marker for metastatic potential. It used to be accepted that only premenopausal women should have their axilla staged by operation as there was a good case for giving chemotherapy to lymph node-positive patients; however, it is now clear that postmenopausal women also benefit from chemotherapy and so all patients require axillary surgery. In postmenopausal patients, tamoxifen was once given regardless of axillary lymph node status, but it is now known that only hormone receptor-positive patients, irrespective of age, benefit from this. Axillary surgery should not be combined with radiotherapy to the axilla because of excess morbidity. Removal of the internal mammary lymph nodes is unnecessary.

Sentinel node biopsy

This technique has become the standard of care in the management of the axilla in patients with clinically node-negative disease. The sentinel node is localised preoperatively by the injection of patent blue dye (Figure 53.28) and radioisotope-labelled albumin in the breast. The recommended site of injection is in the subdermal plexus around the nipple although some still inject on the axillary side of the cancer. The marker passes to the primary node draining the area and is detected visually and with a hand-held gamma camera. Peroperative diagnosis allows completion axillary clearance if nodal disease is detected. This may be achieved with frozen-section analysis, touch imprint cytology (TIC) or by molecular methods. These involve homogenising the node and detection of a gene such as

cytokeratin 19 or mamoglobin. In some cases there are only subcapsular micrometastases that are missed at frozen section. In patients in whom there is no tumour involvement of the sentinel node, further axillary dissection can be avoided. A nomogram outlining the chances of further axillary node positivity has been developed by the group at Memorial Sloan Kettering Hospital, New York, and is available on their website (www.mskcc.org/mskcc/html/15938.cfm). Recent trial results have called into question the utility of completion axillary clearance after a positive sentinel node has been detected but, at present, this remains controversial.

Radiotherapy

Radiotherapy to the chest wall after mastectomy is indicated in selected patients in whom the risks of local recurrence are high. This includes patients with large tumours and those with large numbers of positive nodes or extensive lymphovascular invasion. There is some evidence that postoperative chest wall radiotherapy improves survival in women with node-positive breast cancer.

It is conventional to combine conservative surgery with radiotherapy to the remaining breast tissue. Recurrence rates are too high for treatment by local excision alone except in special cases (small node-negative tumours of a special type). Trials are under way to investigate whether radiotherapy can be given intraoperatively at one sitting or as an accelerated postoperative course. This would have considerable advantages in making conservative surgery available in areas where radiotherapy is not currently used. It would also relieve the burden of the current demand for radiotherapy, which accounts for up to 40 per cent of activity in some departments.

Extrapolation from the Oxford overviews of systemic therapy

Figure 53.27 Radical mastectomy with pectoralis removed; the modified radical approach leaves the pectoralis major muscle intact.

Figure 53.28 Sentinel node biopsy.

(carried out every five years) suggests that for every four local recurrences avoided, one additional life will be spared at 15 years. This means that it is important to get the first treatments right and avoid local recurrence.

Adjuvant systemic therapy

Over the last 25 years there has been a revolution in our understanding of the biological nature of carcinoma of the breast. It is now widely accepted that the outcomes of treatment are pre-determined by the extent of micrometastatic disease at the time of diagnosis. Variations in the radical extent of local therapy might influence local relapse but probably do not alter long-term mortality from the disease. However, systemic therapy targeted at these putative micrometastases might be expected to delay relapse and prolong survival. As a result of many international clinical trials and recent world overview analyses, it can be stated with statistical confidence that the appropriate use of adjuvant chemotherapy or hormone therapy will improve relapse-free survival by approximately 30 per cent, which ultimately translates into an absolute improvement in survival of the order of 10 per cent at 15 years. Bearing in mind how common the disease is in northern Europe and the USA, these figures are of major public health importance.

Who to treat and with what are still questions for which absolute answers have yet to be found, but the data from the overviews of recent trials show that lymph node-positive and many higher risk node-negative women should be recommended adjuvant combined chemotherapy. Women with hormone receptor-positive tumours will obtain a worthwhile benefit from about five years of endocrine therapy, either 20 mg daily of tamoxifen if premenopausal or the newer aromatase inhibitors (anastrozole, letrozole and exemestane) if postmenopausal. It is no longer appropriate to give hormone therapy to women who do not have oestrogen or progesterone receptor-positive disease.

Hormone therapy

Tamoxifen has been the most widely used 'hormonal' treatment in breast cancer. Its efficacy as an adjuvant therapy was first reported in 1983 and it has now been shown to reduce the annual rate of recurrence by 25 per cent, with a 17 per cent reduction in the annual rate of death. The beneficial effects of

tamoxifen in reducing the risk of tumours in the contralateral breast have also been observed, as has its role as a preventative agent (IBIS-I and NSABP-P1 trials). Trials studying the optimal duration of treatment suggest that five years of treatment is preferable to two years.

Other hormonal agents that are also beneficial as adjuvant therapy have been developed. These include the LHRH agonists, which induce a reversible ovarian suppression and thus have the same beneficial effects as surgical or radiation-induced ovarian ablation in premenopausal receptor-positive women, and the oral aromatase inhibitors (AIs) for postmenopausal women. The latter group of compounds are now licensed for treatment of recurrent disease, in which they have been shown to be superior to tamoxifen. A large trial comparing anastrozole to tamoxifen in the adjuvant setting has shown a beneficial effect for the aromatase inhibitor in terms of relapse-free survival, although no benefit for overall survival. There is an additional reduction in contralateral disease, which makes this drug suitable for a study of prevention, and the side-effect profile is different from that of tamoxifen. The AIs have been more expensive than tamoxifen but are all coming off patent protection and generic copies may allow more widespread use. There is an increase in bone density loss with patients on an AI and a bone density scan is advised prior to commencement with treatment of underlying osteopenia or osteoporosis.

Chemotherapy

Chemotherapy using a first-generation regimen such as a six-monthly cycle of cyclophosphamide, methotrexate and 5-fluorouracil (CMF) will achieve a 25 per cent reduction in the risk of relapse over a 10- to 15-year period. It is important to understand that this 25 per cent reduction refers to the likelihood of an event happening. For example, a woman with a 96 per cent chance of survival at, say, five years only has a 4 per cent chance of death over this time and the absolute benefit from chemotherapy would be an increase in survival rate of 1 per cent, to 97 per cent. This would not be a sufficient gain to offset the side effects of this potentially toxic therapy. However, for a woman with a 60 per cent chance of dying (40 per cent survival rate) a 25 per cent reduction in risk would increase her likelihood of survival to 55 per cent and thus treatment would be worthwhile. CMF is no longer considered adequate adjuvant chemotherapy and modern regimens include an anthracycline (doxorubicin or epirubicin) and the newer agents such as the taxanes.

Chemotherapy was once confined to premenopausal women with a poor prognosis (in whom its effects are likely to be the result, in part, of a chemical castration effect) but is being increasingly offered to postmenopausal women with poor prognosis disease as well. Chemotherapy may be considered in node-negative patients if other prognostic factors, such as tumour grade, imply a high risk of recurrence. The effect of combining hormone and chemotherapy is additive although hormone therapy is started after completion of chemotherapy to reduce side effects.

High-dose chemotherapy with stem cell rescue for patients with heavy lymph node involvement has now been shown in controlled trials to offer no advantage and has been abandoned.

Primary chemotherapy (neoadjuvant) is being used in many centres for large but operable tumours that would traditionally require a mastectomy (and almost certainly postoperative adjuvant chemotherapy). The aim of this treatment is to shrink

the tumour to enable breast-conserving surgery to be performed. This approach is successful in up to 80 per cent of cases but is not associated with improvements in survival compared with conventionally timed chemotherapy. For older patients with breast cancers strongly positive for hormone receptors a similar effect can be seen with three months of endocrine treatment.

Newer 'biological' agents will be used more frequently as molecular targets are identified – the first of these, trastuzumab (Herceptin), is active against tumours containing the growth factor receptor c-erbB2. Other agents currently available include bevacizumab, a vascular growth factor receptor inhibitor, and lapatinab, an oral combined growth factor receptor inhibitor. It is unclear how and when these agents will be used, whether in combination or instead of standard chemotherapy agents.

Follow up of breast cancer

Patients with breast cancer used to be followed for life to detect recurrence and dissemination. This led to large clinics with little value for either patient or doctor. It is current practice to arrange yearly or two-yearly mammography of the treated and contralateral breast. There is a move to return the patient early to the care of the general practitioner with fast-track access back to the breast clinic if suspicious symptoms appear. There is currently no routine role for repeated measurements of tumour markers or imaging other than mammography.

Phenomena resulting from lymphatic obstruction in advanced breast cancer

Peau d'orange

Peau d'orange is caused by cutaneous lymphatic oedema. Where the infiltrated skin is tethered by the sweat ducts it cannot swell, leading to an appearance like orange skin. Occasionally, the same phenomenon is seen over a chronic abscess (Figure 53.24).

Late oedema of the arm is a troublesome complication of breast cancer treatment, fortunately seen less often now that radical axillary dissection and radiotherapy are rarely combined. However, it does still occur occasionally after either mode of treatment alone and appears at any time from months to years after treatment. There is usually no precipitating cause but recurrent tumour should be excluded because neoplastic infiltration of the axilla can cause arm swelling as a result of both lymphatic and venous blockage. This neoplastic infiltration is often painful because of brachial plexus nerve involvement.

An oedematous limb is susceptible to bacterial infections following quite minor trauma and these require vigorous antibiotic treatment. Antibiotics may need to be given for much longer than is normal and patients at risk of infection should have antibiotics readily available to enable treatment to be started promptly. Treatment of late oedema is difficult but limb elevation, elastic arm stockings and pneumatic compression devices can be useful.

Cancer-en-cuirasse

The skin of the chest is infiltrated with carcinoma and has been likened to a coat. It may be associated with a grossly swollen arm. This usually occurs in cases with local recurrence after mastectomy and is occasionally seen to follow the distribution of irradiation to the chest wall. The condition may respond to palliative systemic treatment but prognosis in terms of survival is poor.

Lymphangiosarcoma

Lymphangiosarcoma is a rare complication of lymphoedema with an onset many years after the original treatment. It takes the form of multiple subcutaneous nodules in the upper limb and must be distinguished from recurrent carcinoma of the breast. The prognosis is poor but some cases respond to cytotoxic therapy or irradiation. Interscapulothoracic (forequarter) amputation is rarely indicated.

Breast reconstruction

Despite an increasing trend towards conservative surgery, up to 50 per cent of women still require, or want, a mastectomy. These women can now be offered immediate or delayed reconstruction of the breast. Few contraindications to breast reconstruction exist. Even those with a limited life expectancy may benefit from the improved quality of life; however, patients do require counselling before this procedure so that their expectations of cosmetic outcome are not unrealistic.

The easiest type of reconstruction is using a silicone gel implant under the pectoralis major muscle. This may be combined with prior tissue expansion using an expandable saline prosthesis first (or a combined device), which creates some ptosis of the new breast. If the skin at the mastectomy site is poor (e.g. following radiotherapy) or if a larger volume of tissue is required, a musculocutaneous flap can be constructed either from the latissimus dorsi muscle (an LD flap) (Figure 53.29) or using the transversus abdominis muscle (a TRAM flap as shown in Figure 53.30). The latter gives an excellent cosmetic result in experienced hands but is a lengthy procedure and requires careful patient selection. It is now usually performed as a free transfer using microvascular anastomosis, although the pedicled TRAM from the contralateral side is still used. Variations on the TRAM flap requiring less muscle harvesting, such as the DIEP flap (based on deep inferior epigastric vessels), are increasingly being used.

The timing of reconstruction is difficult. Impediments to immediate reconstruction include insufficient theatre time and a lack of experienced reconstructive surgeons. In addition, if a patient is likely to need postoperative radiotherapy then a delayed reconstruction using a flap often gives a better result. Radiotherapy onto a prosthesis often leads to a high incidence of capsular contracture and unacceptable results.

Figure 53.29 Reconstruction with latissimus dorsi flap.

Figure 53.30 Transversus abdominus muscle flap.

Nipple reconstruction is a relatively simple procedure that can be performed under a local anaesthetic. Many different types of nipple reconstruction are described but the majority lose height with time. Tattooing of the reconstructed nipple is often required. Alternatively, the patient can be fitted with a prosthetic nipple. To achieve symmetry the opposite breast may require a cosmetic procedure such as reduction or augmentation mammoplasty, or mastopexy. A breast reconstructive service can be offered by a suitably trained breast surgeon, a plastic surgeon or, ideally, using a combined oncoplastic approach. The patient needs to be warned that breast reconstruction is seldom, if ever, one operation.

External breast prostheses that fit within the bra are the most common method of restoring volume fill and should be available for all women who do not have an immediate reconstruction.

Screening for breast cancer

Because the prognosis of breast cancer is closely related to stage at diagnosis it would seem reasonable to hope that a population screening programme that could detect tumours before they come to the patient's notice might reduce mortality from breast cancer. Indeed, a number of studies have shown that breast screening by mammography in women over the age of 50 years will reduce cause-specific mortality by up to 30 per cent. Following the publication in 1987 of the Forrest report, the National Health Service in the UK launched a programme of three-yearly mammographic screening for women between the ages of 50 and 64 years (now increased to 70 years). The introduction of this programme has undoubtedly improved

the quality of breast cancer services but a number of questions remain unanswered, including the value of screening women under 50 years and the ideal interval between screenings. The psychological consequences of false alarms or false reassurances still need to be addressed and self-examination programmes that have failed to show any benefit for the population in terms of earlier detection of or decreased mortality from breast cancer remain controversial. The opponents of screening rightly point out that some women will have disease detected and treated that might never harm them in their lifetime. However, until we can identify this group and separate them from those in whom prompt diagnosis and treatment will be beneficial, we will continue to treat everyone.

MRI is used to screen those at very high risk or where radiation might be hazardous (Li–Fraumeni syndrome). There is no place for thermography as a screening (or diagnostic) tool.

Familial breast cancer

Recent developments in molecular genetics and the identification of a number of breast cancer predisposition genes (*BRCA1*, *BRCA2* and *p53*) have done much to stimulate interest in this area. Yet women whose breast cancer is due to an inherited genetic change actually account for less than 5 per cent of all cases of breast cancer, that is about 1250 cases per year in the UK and 9000 cases in the USA. A much larger number of women will have a risk that is elevated above normal because of an as yet unspecified familial inheritance. These women have a risk of developing breast cancer that is 2–10 times above baseline. The risks associated with family history are summarised in Table 53.5.

Table 53.5 Likelihood of genetic mutation with family history.

No. of family cases <50 years old	<i>BRCA1</i> (%) ^a	<i>BRCA1</i> (%) ^b
2	4	3
3	17	13
4	41	33
5	55	44

^a*BRCA1* is also associated with ovarian and, to a lesser extent, colorectal and prostate cancer.

^b*BRCA2* is associated with familial male breast cancer.

The *BRCA1* gene has been associated with an increased incidence of breast (and ovarian) cancer and is located on the long arm of chromosome 17 (17q). The gene frequency in the population is approximately 0.0006. It does, however, occur with greater frequency in certain populations such as Ashkenazi Jews, in whom there is often a common (founder) mutation. *BRCA2* is located on chromosome 13q and there is an association with male breast cancer. Women who are thought to be gene carriers may be offered breast screening (and ovarian screening in the case of *BRCA1*, which is known to impart a 50 per cent lifetime risk of ovarian cancer), usually as part of a research programme, or genetic counselling and mutation analysis. Those who prove to be 'gene positive' have a 50–80 per cent risk of developing breast cancer, predominantly while premenopausal. Many will opt for prophylactic mastectomy. Although this does

not completely eliminate the risk, it does reduce it considerably. This work should be carried out in specialist centres.

For the great majority of women with a positive family history, who are unlikely to be carriers of a breast cancer gene, there are no currently proven breast cancer screening manoeuvres, although this is under investigation. Tamoxifen given for five years appears to reduce the risk of breast cancer by 30–50 per cent, and newer agents are currently under trial. Thus, these women are best served by being assessed and followed-up, preferably in a properly organised family history clinic.

Pregnancy

The effects of pregnancy on breast cancer are not well studied but it is thought that breast cancer presenting during pregnancy or lactation tends to be at a later stage, presumably because the symptoms are masked by the pregnancy; however, in other respects it behaves in a similar way to breast cancer in a non-pregnant young woman and should be treated accordingly. Thus, treatment is similar with some provisos: radiotherapy should be avoided during pregnancy, making mastectomy a more frequent option than breast conservation surgery; chemotherapy should be avoided during the first trimester but appears safe subsequently; most tumours are hormone receptor negative and so hormone treatment, which is potentially teratogenic, is not required. Becoming pregnant subsequent to a diagnosis of breast cancer appears not to alter the likely outcome, but women are usually advised to wait at least two years as it is within this time that recurrence most often occurs. The risk of developing breast cancer with oral contraceptive use is only slight, and disappears ten years after stopping the oral contraceptive pill.

Hormone replacement therapy

HRT does increase the risk of developing breast cancer if taken for prolonged periods and in certain high-risk groups. HRT may also prolong symptoms of benign breast disorders such as cysts and mastalgia and make mammographic appearances more difficult to interpret.

Patients who develop breast cancer while on HRT appear to have a more favourable prognosis. The consequences in terms of recurrence in women using HRT following breast cancer are unknown.

Treatment of advanced breast cancer

Breast cancer may occasionally present as metastatic disease without evidence of a primary tumour (that is with an occult primary). The diagnosis is made partly by exclusion of another site for the primary tumour and may be confirmed by histology with special immunohistological stains of the metastatic lesions. Management should be aimed at palliation of the symptoms and treatment of the breast cancer, usually by endocrine manipulation with or without radiotherapy.

Locally advanced inoperable breast cancer

Locally advanced inoperable breast cancer, including inflammatory breast cancer, is usually treated with systemic therapy, either chemotherapy or hormone therapy.

Occasionally, 'toilet mastectomy' or radiotherapy is required to control a fungating tumour but often incision through microscopically permeated tissues results in a worse outcome.

Metastatic carcinoma of the breast

Metastatic carcinoma of the breast will also require palliative systemic therapy to alleviate symptoms. Hormone manipulation is often the first-line treatment because of its minimal side effects. It is particularly useful for bony metastases. However, only about 30 per cent of these tumours will be hormone responsive and, unfortunately, in time, even these will become resistant to treatment. First-line hormone therapy for postmenopausal women is now anastrozole or one of the other third-generation aromatase inhibitors. Tamoxifen, ovarian suppression by surgery (for premenopausal women), radiotherapy and medical treatment are all in common use. When resistance to these has developed, other hormonal agents can prove useful, with about one-half of the response rate seen in the first-line therapy. The newer agents such as anti-progestins, pure anti-oestrogens and growth factor tyrosine kinase inhibitors are all candidates for this role.

Cytotoxic therapy is used particularly in younger women or those with visceral metastases and rapidly growing tumours. A variety of regimens is available and, although none prolongs survival, contrary to expectations, quality of life and symptom control is often better with more aggressive treatments, with responses being seen in up to 70 per cent of patients.

Local treatment may also prove useful for some metastatic disease, such as radiotherapy for painful bony deposits and internal fixation of pathological fractures.

THE MALE BREAST

Gynaecomastia

Idiopathic

Hypertrophy of the male breast may be unilateral or bilateral. The breasts enlarge at puberty and sometimes present the characteristics of female breasts.

Hormonal

Enlargement of the breasts often accompanied stilbestrol therapy for prostate cancer, now rarely used. It may also occur as a result of a teratoma of the testis, in anorchism and after castration. Rarely, it may be a feature of ectopic hormonal production in bronchial carcinoma and in adrenal and pituitary disease. Bodybuilders may use steroids to improve their physique, which may cause gynaecomastia. Some even go so far as to take tamoxifen to mask this symptom.

Associated with leprosy

Gynaecomastia is very common in men suffering from leprosy. This is possibly because of bilateral testicular atrophy, which is a frequent accompaniment of leprosy.

Associated with liver failure

Gynaecomastia sometimes occurs in patients with cirrhosis as a result of failure of the liver to metabolise oestrogens. It is associated with drugs that interfere with the hepatic metabolism of oestrogens. It is also seen with certain drugs such as cimetidine, digitalis and spironolactone.

Associated with Klinefelter syndrome

Gynaecomastia may occur in patients with Klinefelter's syndrome, a sex chromosome anomaly having 47XXY trisomy.

Figure 53.31 Carcinoma of the male breast.

Treatment

Provided that the patient is healthy and comparatively young, reassurance may be sufficient. If not, mastectomy with preservation of the areola and nipple can be performed. The patient must be warned about the side effects of this procedure, which are common and a cause of many medicolegal complaints in the UK.

Carcinoma of the male breast

Carcinoma of the male breast (Figure 53.31) accounts for less than 0.5 per cent of all cases of breast cancer. The known predisposing causes include gynaecomastia and excess endogenous or exogenous oestrogen. As in the female, it tends to present as a lump and is most commonly an infiltrating ductal carcinoma.

Treatment

Stage for stage the treatment is the same as for carcinoma in the female breast and prognosis depends upon stage at presentation. Adequate local excision, because of the small size of the breast, should always be with a 'mastectomy'.

OTHER TUMOURS OF THE BREAST

Lipoma

A true lipoma is very rare.

Sarcoma of the breast

Sarcoma of the breast is usually of the spindle-cell variety and accounts for 0.5 per cent of malignant tumours of the breast. Some of these growths arise in an intracanalicular fibroadenoma or may follow previous radiotherapy, e.g. for Hodgkin's lymphoma, many years previously. It may be impossible to distinguish clinically a sarcoma of the breast from a medullary carcinoma, but areas of cystic degeneration suggest a sarcoma and on incising the neoplasm it is pale and friable. Sarcoma tends to occur in younger women between the ages of 30 and 40 years. Treatment is by simple mastectomy followed by radiotherapy. The prognosis depends on the stage and histological type.

Metastases

On rare occasions cancer elsewhere may present with a metastasis in the breast. The breast is also occasionally infiltrated by Hodgkin's disease and other lymphomas.

LEARNING OBJECTIVES

To understand:

- The important role of surgery in cardiac disease
- The role of investigation in planning surgery
- The management of coronary heart disease
- The role of surgery in valvular heart disease
- The special role of surgery in congenital heart disease
- The management of aortic vascular and pericardial disease

INTRODUCTION

In 1925, Sir Henry Souttar reported the first mitral commissurotomy in the *British Medical Journal*. He wrote that the heart should be as amenable to surgery as any other organ. He saw the main problem as being maintenance of blood flow, particularly to the brain, while surgery was being performed.

The first real advances occurred in the late 1940s and early 1950s, driven by surgeons who had gained confidence and experience under the pressures and opportunities provided by war, followed by the development of cardiopulmonary bypass in the mid-1950s. Recently, the well-being and lifespan of patients with congenital, valvular and degenerative heart disease has improved drastically due to the advances in the range, complexity, and technical expertise in cardiac surgery.

CARDIOPULMONARY BYPASS

Cardiopulmonary bypass (CPB) was first used successfully in 1953 by Gibbon and has since revolutionised cardiac surgery. It can be employed in any procedure in which the heart and lungs need to be stopped temporarily and their function replaced artificially. Before Gibbon's work, valve surgery under direct vision would not have been possible nor would the precise reconstructions needed to treat extensive coronary artery disease. Much of the success of modern CPB is attributable to the development of new biomaterials and sophisticated oxygenating devices, as well as a greater understanding of the pathophysiological consequences of CPB (Summary box 54.1).

Surgical approach to the heart

The heart is approached mainly by a median sternotomy. An incision is made from the jugular or suprasternal notch to the lower end of the xiphisternum. The sternum is divided and retracted to expose the thymus superiorly and the pericardium inferiorly. The thymus, although atrophic in adults, often remains relatively vascular. The thymus and pleurae are

Summary box 54.1

Alternative uses of CPB

- Rewarming from profound hypothermia
- Resuscitation in severe respiratory failure
- As an adjunct in pulmonary embolectomy
- In single- and double-lung transplantation
- In cardiopulmonary trauma
- In certain non-cardiac surgical procedures (e.g. resection of highly vascular tumours and tumours invading large blood vessels)

dissected from the pericardium, and the pericardium is opened. Before cannulation for CPB, the patient is fully heparinised. Other incisions which can be used include left anterolateral thoracotomy.

Initiating cardiopulmonary bypass

Arterial cannulation

Conventionally, the great vessels are exposed and an aortic perfusion cannula is inserted into the ascending aorta, held in place by the purse-string suture. Air is excluded and the cannula connected to the bypass circuit. Alternatively, when it is inadvisable (aortic dissection), impractical (aortic root surgery) or impossible (severe adhesions) to cannulate the aorta, alternative arterial cannulation sites can be used, such as the femoral artery or the axillary artery.

Venous cannulation

A second purse-string suture is inserted into the right atrium by the appendage. A single 'two-stage' venous cannula placed in the right atrium establishes venous drainage. The venous pipe has end holes that sit in the inferior vena cava and side holes that sit in the right atrium (to take the drainage from the superior vena cava). Alternatively, the superior and inferior

vena cavae may be cannulated separately to gain better control over the venous return and to facilitate surgery within the right atrium. Venous drainage from the femoral vein can offer an alternative, particularly during thoracic aortic procedures.

Cardiopulmonary bypass circuit

Once the circuit is connected (Figure 54.1), the CPB machine (the 'pump') gradually takes over the processes of circulation and ventilation. Once full flow is established (the required cardiac output depends on the body surface area of the patient), the ventilator is stopped and the heart can be isolated from the rest of the circulation. Blood is pumped from a venous reservoir and oxygenated using an oxygenator that allows gas exchange across its membrane.

The core systemic temperature can be lowered by passing the returning blood through a heat exchanger which can reduce the metabolic demands of the tissues. The degree of cooling is according to the severity and complexity of the surgical procedure, as well as the surgeon's preference.

The blood is also filtered to remove particulate emboli and returned to the systemic arterial circulation via a pump. Suction pumps can be employed to keep the area around the heart clear of blood, and to decompress the heart when used as vents.

Myocardial protection

Once CPB has been established, the ascending aorta is usually cross-clamped to obtain a bloodless operative field. The heart ceases to eject and becomes anoxic due to inhibition of coronary blood flow. Permanent myocardial damage can develop within 15–20 minutes, therefore most cardiac operations require some form of myocardial protection. Techniques of myocardial protection and the operative management of the myocardium have

had a significant impact on the complexity of cardiac surgery. The methods of myocardial protection include intracoronary infusion of a cardioplegic solution, intermittent cross-clamp fibrillation and total circulatory arrest.

Cardioplegic solutions vary in terms of temperature, pH, arresting agent, osmolality, and the presence of red cells and other factors. Most solutions contain potassium as the arresting agent. Potassium arrests the heart in diastole by depolarisation of the membrane. Cold (4–10°C) isotonic crystalloid or blood solutions aid myocardial protection by reducing metabolic requirements through local hypothermia. Warm cardioplegic solutions, on the other hand, may facilitate better myocardial repair recovery postoperatively by aiding intramycocardial enzyme activation.

Intermittent cross-clamp fibrillation is a technique in which intermittent ventricular fibrillation is induced by a small electrical charge. The heart does not eject and is relatively still, but not bloodless. The aorta is cross-clamped to render the heart ischaemic. The heart can tolerate short periods (10–20 minutes) of intermittent ischaemia, providing the heart is reperfused when the cross-clamp is released and allowed to beat following cardioversion for short periods during the operation.

Total circulatory arrest becomes necessary when visibility and clarity of the operative area is crucial, as in paediatric surgery or in surgery of the ascending aorta and arch of the aorta. CPB is instituted and the core body temperature reduced to 15–18°C (profound hypothermia). The metabolic rate of all organs of the body is reduced by 50 per cent with every 7°C drop in temperature. Using this technique, circulatory arrest can be tolerated for 20–30 minutes. Additional cerebral protection can be provided with ice packs placed around the head, pharmacological agents, and cerebral perfusion techniques.

Discontinuing cardiopulmonary bypass

At the end of the procedure, air must be meticulously excluded from the cardiac chambers. Once perfusion is restored to the coronary arteries (by removing the cross-clamp) the heart may beat spontaneously. If ventricular fibrillation is present, cardioversion may be required. Epicardial pacing wires may be placed to treat postoperative bradycardia or heart block. The patient is rewarmed, acidosis and hypokalaemia are corrected, and ventilation is restarted. The heart gradually takes over the circulation while the arterial flow from the CPB machine is reduced. When the blood pressure is acceptable and the surgeon is confident that the heart function is adequate, CPB is discontinued. The cannulae are removed and the anticoagulation is reversed by using protamine.

Complications of cardiopulmonary bypass

CPB is a complex technique and requires careful management between surgeon, anaesthetist and perfusionist to ensure that the patient remains safe. Difficulties can occur during cannulation (arterial tear), at the start of CPB (oxygenator failure) and at the end of CPB (coagulopathy). A summary is given in Summary box 54.2. Many complications can occur following blood exposure to the non-physiological surface of the CPB circuit. This leads to the activation of inflammatory cascades giving rise to a post-CPB systematic inflammatory response syndrome (SIRs) that can ultimately lead to multiorgan failure.

Recent developments include 'off-pump' surgery where the surgery is performed on the beating heart with the aid of stabilisers and minimal (mini) bypass, where all the elements of

Figure 54.1 Components of the cardiopulmonary bypass (CPB) circuit. (Reproduced from Abraham JK. Cardiopulmonary bypass. Surgery 2000; 18: 11, with permission from The Medical Publishing Company.)

conventional bypass are made as compact as possible to eliminate the potential inflammatory effects.

Summary box 54.2

Potential complications of CPB

- Bleeding disorders
- Infection
- Air embolism
- Intestinal ischaemia/infarction
- Microembolisation
- Myocardial depression
- Neurological dysfunction
- Pancreatitis
- Post-cardiotomy syndrome
- Pulmonary injury
- Systemic organ dysfunction
- Vascular injury

improved survival after surgery. With the advent of percutaneous coronary intervention (PCI) in the 1980s, the patient population undergoing CABG has changed, becoming progressively sicker but often with the most to gain. Over the last decade, there have been major advances in PCI including the use of bare metal stents and the development of drug-eluting stents in an effort to reduce restenosis. The role of CABG in the treatment of ischaemic heart disease is continually questioned and less invasive therapies are being sought. A recent large multicentred trial compared CABG to PCI with drug-eluting stents and showed that CABG is still the 'gold standard' in certain groups of patients (Summary box 54.3).

Summary box 54.3

Coronary artery surgery

- Randomised controlled trials have confirmed improvement in survival following CABG for certain groups of patients

CORONARY ARTERY BYPASS SURGERY

Introduction

Before the 1950s, surgical attempts to treat coronary artery disease (CAD) through augmentation of non-coronary flow to the myocardium via the creation of pericardial or omental adhesions had limited success. From the 1960s, the importance of aorto-coronary saphenous vein grafts and the value of the internal mammary (internal thoracic artery) were increasingly recognised. The outcomes of coronary artery bypass graft (CABG) surgery were carefully monitored from the beginning and by the 1970s multiple large, prospectively randomised, multicentre trials were conducted. All showed that a subset of patients had

Coronary artery anatomy

The coronary arteries are branches of the ascending aorta, arising from ostia in the aortic sinuses above the aortic valve, the right from the anterior sinus and the left from the left posterior sinus (Figure 54.2).

Left coronary artery

The left main coronary artery, which arises from the aortic root, can be the site of significant stenosis ('left main stem disease') and carries the worst prognosis in terms of survival without surgery. The artery is inaccessible at its origin and therefore grafts are anastomosed to its branches, the left anterior

Figure 54.2 The heart, showing the distribution of the left and right coronary arteries. (a) Anterior surface of the heart and (b) base and diaphragmatic surface of the heart.

descending (LAD) artery or anterior interventricular artery and obtuse/marginal (OM) branches of the circumflex artery. The LAD is the most frequently diseased coronary artery and most often bypassed during CABG surgery.

Right coronary artery

The right coronary artery (RCA) passes from its origin anteriorly between the right atrial appendage and the pulmonary trunk and courses in the atrioventricular groove around the margin of the right ventricle. It continues as the posterior descending artery or interventricular artery. Common sites of stenosis of the RCA are in its proximal portion or at the bifurcation or crux. In the presence of disease at the bifurcation, a graft can be placed distally to the posterior descending artery.

The question of anatomical dominance is determined by the artery that supplies the posterior descending artery. In approximately 90 per cent of cases, the posterior descending artery arises from the RCA, a pattern referred to as 'right dominance'. The posterior descending artery can also arise from the circumflex artery, a pattern referred to as 'left dominance', which occurs in approximately 10 per cent of cases. A balanced pattern is one in which two posterior descending arteries, one arising from the right coronary artery and one from the circumflex artery, can exist (Figure 54.2).

Ischaemic heart disease

Ischaemic heart disease (IHD) is a major cause of morbidity and mortality in developed countries. The underlying pathology is mainly atherosclerosis of the coronary arteries.

Pathophysiology

Atherosclerosis is the process underlying the formation of focal obstructions or plaques in large- and medium-sized arteries. It is accepted that atherosclerosis is a chronic inflammatory process resulting from interactions between plasma lipoproteins, leukocytes (monocyte/macrophages, T lymphocytes), vascular endothelial cells, and smooth muscle cells. Atherosclerotic lesions can histologically be found at different stages in blood vessels including:

- **The fatty streak.** The first evidence of atherosclerosis can be found in children 10–14 years of age. This appears as a yellow streak running along the major arteries. The streak consists of smooth muscle cells, which are filled with cholesterol, and foam cells.
- **Fibrous plaque.** A fibrous plaque consists of large numbers of smooth muscle cells, foam cells, and leukocytes. As the fibrous plaque grows, it projects into vessels leading to narrowing of the lumen, which in turn can lead to ischaemia or infarction.
- **Complicated lesion.** This occurs when the fibrous plaque ruptures, provoking activation of the coagulation cascade and the formation of thrombi.

Clinical manifestations

The principal symptoms of IHD are chest pain or angina, breathlessness, fatigue, swelling, palpitations and syncope. Severity of symptoms and the extent to which the symptoms interfere with everyday activities form a significant part of the clinical history. An assessment of risk factors should be included (Summary box

54.4). Clinical examination follows and, although often normal, any evidence of myocardial ischaemia or stigmata of associated disease, such as diabetes or peripheral vascular disease, should be noted.

Summary box 54.4

Risk factors for IHD

- Advancing age
- Male gender
- Hyperlipidaemia
- Diabetes mellitus
- Hypertension
- Smoking
- Family history of IHD
- Obesity
- Reduced physical activity

Investigations

Non-invasive methods of diagnosis

Resting electrocardiography

As a baseline test, a 12-lead resting electrocardiogram (ECG) often provides the first indication of ischaemic cardiac disease and is essential in the acute clinical setting. However, it is not necessarily abnormal even in the presence of severe multivessel coronary heart disease. Evidence of previous myocardial infarction is seen commonly as Q waves and/or non-specific ST and T-wave changes.

Troponin and cardiac isoenzymes

These are useful in assessing patients with an acute coronary syndrome (ACS) when the diagnosis is in doubt. Standard enzyme measurement such as Troponin, creatine kinase MB (CKMB), and lactate dehydrogenase (LDH) can aid diagnosis, as well as having prognostic implications.

Exercise tolerance testing

Exercise tolerance testing (ETT) is a valuable technique for assessing myocardial ischaemia, both for diagnostic purposes and as a prognostic tool. However, an abnormal exercise test must be interpreted in the light of the probability of coronary artery disease and the physiological response to exercise as measured by the percentage of the maximum predicted heart rate achieved. A positive test with evidence of ischaemia on the ECG (ST depression of ≤ 2 mm) does not always indicate IHD, and a negative test does not always exclude its presence.

Echocardiography

Performed either through a transthoracic or transoesophageal approach, it is valuable for the evaluation of ventricular function and regional wall motion abnormalities, as well as valvular lesions.

Stress echocardiography can detect regional wall motion abnormalities brought on by exercise or the use of dobutamine or dipyridamole. It is a reliable method of identifying viable myocardium. Impaired but recoverable myocardium possesses a functional reserve that allows it to be temporarily recruited into action, whereas scar tissue does not. The development of

real time three-dimensional ECHO (RT3DE) with the ability to carry out valve construction from different surfaces has recently revolutionised preoperative surgical planning in patients with complex valvular diseases.

Radionuclide studies and cardiac magnetic resonance imaging

The two main types of radionuclide study available are perfusion and blood pool studies. They allow an assessment of the perfusion and cellular integrity of viable myocardium. Cardiac magnetic resonance imaging (MRI) can be performed to evaluate the structure and function of the heart and blood vessels and offers an alternative to angiography.

Positron emission tomography

Positron emission tomography (PET) provides information on myocardial perfusion, metabolism and cell membrane function. Positron-emitting isotopes are used to label physiological substances, after which the regional distribution of these substances can be measured. PET is valuable in the diagnosis of coronary artery disease, particularly when the more widely available imaging modalities are inconclusive. It can identify injured but viable myocardium that is potentially salvageable by revascularisation.

Computed tomography

With the development of the latest computed tomography (CT) scanners, which have the ability to correct for respiratory and cardiac movements, multislice high-resolution CT scanning may become an alternative to coronary angiography. It allows for the assessment of coronary disease, particularly proximal coronary artery disease, and gives some information about the degree of coronary artery calcification.

Invasive methods of diagnosis

Coronary angiography

Selective coronary angiography provides the means of accurately diagnosing the presence and extent of coronary artery disease and remains the 'gold standard' diagnostic technique (Figure 54.3).

Figure 54.3 Coronary angiogram demonstrating severe stenosis in the left main stem prior to bifurcation of the left anterior descending and circumflex arteries.

In spite of the availability of newer imaging techniques, such as cardiac MRI, selective coronary angiography provides high image quality, demonstrating the extent, severity and location of coronary artery stenoses and the quality and size of the distal coronary arteries. Any stenosis in an artery of >70 per cent of the diameter (90 per cent reduction on cross-sectional area) is considered 'severe'. In addition, it allows assessment of ventricular function and provides the cardiac surgeon with information to determine operability, operative risk and probability of operative result. This test only outlines the coronary anatomy, does not demonstrate ischaemia and carries an overall complication rate of less than 1 per cent (Summary box 54.5).

Summary box 54.5

Coronary angiography

- 'Gold standard' for imaging of anatomy
- Demonstrates extent, severity and location of stenoses
- Reduction in diameter of >70 per cent is considered severe (90 per cent reduction in cross-sectional area)
- Demonstrates quality and size of distal arterial tree
- Aids diagnosis of ischaemia
- Evaluates suitability for surgery
- Aids in prognostic assessment

Indications for surgery

The decision to offer CABG is based on the balance between the expected benefit and the risks that the patient faces. The two issues to be addressed when deciding if a patient is suitable to have surgery are the appropriateness of revascularization, and the relative merits of CABG versus PCI.

Current best evidence shows that revascularization can be readily justified on symptomatic grounds in patients with persistent limiting symptoms (angina or angina equivalent) despite optimal medical therapy and/or on prognostic grounds in certain anatomical patterns of disease.

Recent guidelines on myocardial revascularization have been released by the Task Force on Myocardial Revascularization of the European Society of Cardiology (ESC) and the European Association for Cardio-Thoracic Surgery (EACTS) and identified patients with certain angiographic features who can benefit from surgery (Summary box 54.6).

Summary box 54.6

Indication for surgery

- >50 per cent stenosis of the left main stem ('critical left main stem disease')
- >50 per cent stenosis of the proximal left anterior interventricular artery
- Two or three main coronary arteries diseased ('triple-vessel disease')
- Poor ventricular function associated with multi-vessel disease

Chronic stable angina

Although PCI is increasingly being used for the treatment of stable angina, CABG is still indicated in the presence of

certain angiographic features. Angina can be relieved by surgical revascularisation in most patients and symptomatic improvement can be expected for over ten years.

Acute coronary syndromes

A recently published meta-analysis showed substantial benefit with an early invasive strategy mainly in high risk patients. An invasive strategy always starts with angiography. After defining the anatomy and its associated risk features, a decision about the type of intervention can be made. The angiography in combination with ECG changes often identifies the culprit lesion and PCI, if desirable, can be recommended to treat the culprit lesion. Angiography should be performed urgently for diagnostic purposes in patients at high risk and in whom the differential diagnosis of other acute clinical situations is unclear. In stabilized patients after an episode of ACS, surgical indications are similar to those with stable chronic disease.

The optimal timing of revascularization is different for PCI and for CABG. While the benefit from PCI in patients with NSTEMI-ACS (non-ST-segment elevation acute coronary syndrome) is related to its early performance, the benefit from CABG is greatest when patients can undergo surgery after several days of medical stabilization.

Surgery for the complications of myocardial infarction

Myocardial infarction (MI) leads to myocyte necrosis, which may heal to form scar tissue or rupture if the ventricular wall gives way. Free rupture of the ventricle is usually fatal despite treatment. Ventricular septal rupture typically presents 3–7 days after infarction with pulmonary oedema, a pansystolic murmur and hypotension. The diagnosis is usually confirmed with echocardiography. Repair is with a pericardial or artificial Dacron patch. Papillary muscle necrosis causes acute mitral regurgitation, a pansystolic murmur and pulmonary oedema. Diagnosis is made by echocardiography and right heart catheterisation (showing large V waves). Mitral valve replacement is usually necessary, but the mortality rate is higher than in valve replacement for rheumatic heart disease as a result of the associated coronary artery disease. Ventricular aneurysm occurs following partial-thickness necrosis of the ventricular wall if the free wall is replaced with non-contractile fibrous tissue. Left ventricular function is affected because the fibrous wall balloons out during systole and reduces the actual stroke volume. Repair is undertaken using CPB, and CABG is undertaken at the same time if necessary combined with valve replacement.

Patients undergoing valve replacement usually have coronary bypass surgery to any significant coronary lesions. However, several variables need to be carefully evaluated when considering the choice of a combined procedure and the overall operative risk: these include age >70 years, female sex and poor left ventricular function, as well as what the underlying valve pathology is and which valve is to be replaced.

Acute failure of percutaneous coronary angioplasty

Since the advent of intracoronary stents, the need for emergency CABG following complications of percutaneous transluminal coronary angioplasty (PTCA) is low at <1 per cent. The mortality rate in this group is significantly higher than for elective CABG.

Preparation for surgery

Clinical assessment

Before CABG, the severity and stability of the patient's IHD, the presence of significant valvular disease and the status of left ventricular function should be properly evaluated.

Any comorbid risk factors for IHD should be documented and, in particular, the state of coexisting diseases assessed. Attention is paid to the presence of carotid artery disease, peripheral vascular disease, respiratory status, preoperative diabetic control and presence of associated diabetic complications, significant renal dysfunction or coagulopathy. All medications taken by the patient are noted. Ideally, some should be stopped before surgery, in particular any anti-platelet agents, including aspirin and anti-coagulants, as well as oral hypoglycaemics. Others drugs, such as diuretics and angiotensin-converting enzyme (ACE) inhibitors, are stopped on the discretion of the surgeon. However, apart from the exceptions noted, as a general rule all cardiac and anti-hypertensive medications should be taken preoperatively.

Risk assessment

Myocardial revascularization is appropriate when the expected benefits, in terms of survival or health outcomes exceed the expected negative consequences of the procedure. Therefore, risk assessment is an important aspect of contemporary clinical practice, being of value to clinicians and patients. Over the long term, it allows quality control and the assessment of health economics. Numerous different models have been developed for risk stratification in cardiac surgery including the EuroSCORE and STS (Society of Thoracic Surgeons).

The EuroSCORE validated to predict surgical mortality was recently shown to be an independent predictor of major adverse cardiac events (MACE). Therefore, it can be used to determine the risk of revascularization irrespective of, and even before, the selection of treatment strategy. However, it is important to acknowledge that no risk score can accurately predict events in an individual patient. Moreover, limitations exist with all databases used to build risk models, and differences in definitions and variable content can affect the performance of risk scores when they are applied across different populations. Ultimately, risk stratification should be used as a guide, while clinical judgement and multidisciplinary discussion (heart team) remain essential.

Selection of conduit

Venous grafts

The long saphenous vein is the most common vein used as a conduit as it is straightforward to harvest, provides good length and is easy to handle. The ten-year patency rate for long saphenous vein grafts is reported to be 50–60 per cent, with 10–15 per cent occluding in one year. However, recent studies suggest that the early use of lipid-lowering agents and anti-platelet agents, such as low-dose aspirin, can improve vein graft long term patency. In assessing the patient preoperatively, the legs should be checked for varicose veins. Alternative vein conduits include the short saphenous vein or upper limb veins, such as the cephalic vein.

Arterial grafts

The left internal mammary artery (LIMA) or internal thoracic artery has become the conduit of choice for the LAD. Since the mid-1980s, long patency rates of >98 per cent have been reported, with improved long-term survival and fewer reoperations. As

LIMA–LAD anastomosis avoids the late complication of vein graft atherosclerosis, particular interest has focused on the use of bilateral internal mammary artery (BIMA) grafts. However, there is still debate regarding the appropriateness in certain subgroups of patients, such as the obese diabetic in whom sternal wound complications appear higher.

The use of the radial artery as a second or alternative arterial bypass graft has enjoyed a revival. This has been driven to some extent by the developing concept of total arterial revascularisation and the belief that this will help improve long-term results of coronary surgery. Recent randomised controlled studies in the United States and UK have demonstrated excellent patency rates at one and five years. In assessing a patient in whom a radial artery harvest is planned, an Allen's test is performed (Summary box 54.7). Alternative arterial bypass grafts include the gastroepiploic artery and the inferior epigastric artery.

Figure 54.4 The long saphenous vein is exposed at the ankle, anterior to the medial malleolus, as far as the saphenofemoral junction (if required). The side branches are tied carefully and divided, and the vein is excised. Gentle distension of the vein through a cannula at its distal end allows inspection for leaks.

Figure 54.5 A pedicled left internal mammary artery is dissected off the chest wall and divided distally after systemic heparinisation. It is left attached to the subclavian artery proximally.

Summary box 54.7

Allen's test

- The patient makes a tight fist while the surgeon compresses both distal and ulnar arteries digitally; this squeezes blood from the hand
- The hand is then relaxed and compression of the ulnar artery is released; the speed of returning colour to the hand is assessed
- If colour returns in 5–7 seconds, patency and collateral flow from the ulnar artery is confirmed

The operation

Intraoperative monitoring includes monitoring of continuous central venous pressure and blood pressure (via a central line in the internal jugular or subclavian vein and radial artery line, respectively), urine output via a urinary catheter, temperature using a probe positioned at the nasal septum, and the ECG.

The operation commences with harvesting of the conduits (long saphenous vein from the leg (Figure 54.4) or/and radial artery), while the chest is opened via a median sternotomy and the LIMA is dissected from the chest wall (Figure 54.5). The patient is typically placed on CPB after heparinising, the aorta is cross-clamped and the heart arrested with cardioplegia. The grafts are anastomosed to coronary arteries distal to the stenosis (Figure 54.6).

The aortic cross-clamp is removed and the heart is reperfused with oxygenated blood. A side-biting clamp is applied to the ascending aorta and the proximal anastomoses are completed. Occasionally, the surgeon may opt to carry out the whole operation while the cross-clamp is applied to reduce the risks associated with aortic manipulation. The patient is warmed and weaned from CPB. The heparin is reversed and the patient is returned to the intensive care unit (ICU).

Figure 54.6 Completed coronary artery bypass grafts.

Postoperative recovery

The majority of patients are extubated a few hours after returning from surgery and remain in the ICU for 24 hours or so. In some centres, 'fast tracking' appropriate patients allows for an earlier transfer to a recovery area or high-dependency unit (HDU). Discharge is routinely 4–8 days after surgery.

Postoperative complications

Bleeding

Significant bleeding occurs in approximately 2–3 per cent of patients. Rarely, acute cardiac tamponade or profound hypotension may occur in the early postoperative period and requires emergency re sternotomy.

Arrhythmias

The most common postoperative arrhythmia is sinus tachycardia, closely followed by atrial fibrillation (AF). It occurs in around 30 per cent of patients undergoing CABG and often spontaneously reverts to sinus rhythm. Treatment includes correction of potassium (>4.5 mmol/L), the use of amiodarone or digoxin and, if necessary, cardioversion. Bradycardia is seldom seen, but temporary pacing via epicardial pacing wires inserted intraoperatively may be required in the postoperative period.

Poor cardiac output state

Myocardial function typically declines in the first few hours following cardiac surgery, presumably in response to an ischaemia/reperfusion-type injury. Often, inotropic agents are required at

this time to support the heart and circulation. Occasionally, the patient develops a persistent low cardiac output state. The clinical manifestations of such a situation include poor peripheral perfusion, with poor urine output, a developing metabolic acidosis and low blood pressure.

There are several mechanisms that account for this complication in the early postoperative period, including depressed myocardial contractility, reduced preload, increased afterload and a disturbance in heart rate or rhythm.

Treatment is aimed at the underlying cause, but generally includes oxygenation, optimising preload, reducing afterload, managing any rhythm disturbances and improving contractility. If the low cardiac output state persists, the heart may require pharmacological or mechanical support.

Pharmacological support

Inotropic drugs act in a variety of ways to alter the systemic vascular resistance, increase the heart rate and increase the force of myocardial contractility. Commonly used inotropes include isoprenaline, dopamine, dobutamine, adrenaline (epinephrine) and noradrenaline (norepinephrine); they are often used in conjunction with vasodilating agents that decrease the afterload.

Mechanical support

If low cardiac output persists despite inotropic support, the heart may require mechanical support while it recovers its function. Mechanical support can be achieved by using an intra-aortic balloon pump (IABP) counterpulsation, or a ventricular assist device (VAD).

IABP is a device that is inserted, either percutaneously or under direct vision, into the common femoral artery. It is threaded into the aorta until its tip lies just distal to the arch vessels (Figure 54.7). The balloon is triggered by the ECG, deflating during ventricular systole (thus reducing afterload) and inflating in diastole (displacing blood that perfuses the coronary arteries retrogradely). When the heart has recovered sufficiently, the balloon is removed.

VAD is a mechanical circulatory supporting device used to replace the function of a failing heart partially or completely. It can be used as a short-term measure typically for patients recovering from heart attacks or heart surgery, or as a long-term support for patients suffering from congestive heart failure. VAD pumps can be pulsatile which mimic the natural pulsing action of the heart, or continuous flow pumps. Blood is exposed in these devices to a non-biologic surface which can activate proinflammatory and coagulation cascades leading to strokes and bleeding. Another important complication associated with VAD is infection which can be caused by Gram-positive bacteria, Gram-negative bacteria, and fungi.

Neurological dysfunction

Stroke leading to a focal neurological deficit occurs in approximately 2 per cent of patients following CABG. Embolisation, probably originating from the aortic arch or heart chambers, is the most common mechanism for territorial infarcts, with hypoperfusion leading to watershed infarcts. Diffuse neurological injury may occur leading to more subtle cognitive abnormalities in memory, concentration and attention.

Wound infection

Significant deep wound infection resulting in sternal dehiscence and mediastinitis occurs in around 0.5–2 per cent of patients.

Figure 54.7 Intra-aortic balloon pump counterpulsation. (a) The balloon deflates during systole and thereby lowers systemic resistance. It inflates during diastole and increases coronary perfusion in addition to augmenting the systemic blood pressure. (b) The pressure changes and phases of the electrocardiogram (ECG) are shown.

This can be associated with significant morbidity with a prolonged hospital stay and further surgical interventions for debridement and/or rewiring of the sternum. It still has a significant mortality rate of as high as 40 per cent. Wound infections are more common in diabetics and the obese.

Mortality

In the UK, the overall mortality rate for patients undergoing CABG is 2–3 per cent. Multiple factors have been demonstrated to affect mortality after CABG, including age, gender, left ventricular function, use of LIMA and complete revascularisation.

Surgical outcome

Relief of symptoms

If revascularisation is complete, CABG alleviates or improves anginal symptoms in more than 90 per cent of patients at one year; this falls to 80 per cent at five years and 60 per cent at ten years. This symptomatic deterioration usually reflects progression of atherosclerotic disease in vein grafts and native coronary arteries.

Survival

Early surgical versus medical studies have reported survival rates to be 95 per cent at one year, 90 per cent at five years, 75 per cent at ten years and 60 per cent at 15 years. Through changes in surgical practice, such as an increased use of arterial conduits and the widespread use of dual antiplatelet therapy, B-blockers, and lipid-lowering agents, post-CABG survival may well improve in the future (Summary box 54.8).

Summary box 54.8

Coronary artery bypass surgery outcome

Mortality

- 2–3 per cent

Peroperative infarct

- 2–3 per cent

Angina

- Better in 90 per cent at one year
- 80 per cent at five years
- 60 per cent at ten years

Survival

- 95 per cent at one year
- 90 per cent at five years
- 75 per cent at ten years
- 60 per cent at 15 years

Off-pump coronary artery surgery

CABG without the use of CPB is a well-established and increasingly popular method that may be combined with a minimally invasive approach or carried out through a conventional sternotomy. It offers the advantages that it avoids the physiological stress associated with CPB and, to some extent, the aortic manipulation that can lead to neurological injury through atherosclerotic embolisation. Since the introduction of cardiac stabilising devices, such as the Octopus® (Figure 54.8), off-pump coronary artery bypass (OPCAB) grafting has become widespread. One of the concerns, however, associated with off-pump surgery is related to the quality of anastomosis as its carried out on a beating heart and bloody field which can limit the surgeon's vision.

Figure 54.8 Off-pump coronary artery bypass using an Octopus stabiliser to perform the distal anastomosis.

The advantages of off-pump surgery over on-pump has recently been questioned especially with the development and use of the mini-bypass machines which offer a closed circuit and minimal unphysiological surface area, though reducing proinflammatory activation, but at the same time allow the surgeon to operate on a still heart in a bloodless field.

Minimal access surgery

Minimally invasive direct coronary artery bypass (MIDCAB) grafting is performed through a strategically placed minimal access incision and so avoids all invasive aspects of conventional CABG. Through an anterior submammary incision, the LIMA can be dissected down with the aid of a thoracoscope and grafted to the LAD. More lateral MIDCAB incisions allow access to other coronary vessels including branches of the circumflex artery. Patient selection remains, at least at present, a restriction to the ever-increasing minimally invasive methods being developed. Although not yet critically evaluated, one particular approach is to combine MIDCAB (typically LIMA to LAD) with PCI to other less accessible coronary arteries ('hybrid' coronary revascularisation).

VALVULAR HEART DISEASE

Introduction

Early surgical management of valvular heart disease concentrated on valvular repair. The heroic early procedures for valve stenosis were closed and therefore 'blind' commissurotomies. They were replaced by open procedures with full visualisation allowing precise repair and replacement. The first prosthetic valve replacement was performed by Harken in 1960 replacing the aortic valve, followed by a mitral valve replacement by Starr

Dwight Emory Harken, 1910–1993, formerly Chief of Thoracic Surgery, The Peter Bent Brigham Hospital, Boston, MA, USA. Innovator in heart surgery, introduced the concept of intensive care unit and opened the first intensive care unit in 1951. Served as Chief of Thoracic Surgery at Harvard University for 22 years.

Albert Starr, born 1926, formerly Professor of Surgery, The University of Oregon, Portland, OR, USA. Medical Director, Providence Heart and Vascular Institute, Portland. Inventor of the world's first durable artificial mitral valve; winner of Lasker award in 2007 – an award given by the Lasker Foundation in the United States to a person (or persons) who has made major contributions to medical science or who has performed public service on behalf of medicine.

Table 54.1 Comparing options for heart valve surgery.

	Advantages	Disadvantages
Valve repair	Preservation of integral structures Improved haemodynamics Avoids long-term anticoagulation	Technical difficulties Variable failure rate
Valve replacement		
Mechanical	Readily available Extensive experience of use Used in any age group Durability, lifelong	Needs lifelong anticoagulation Susceptibility to infection
Biological		
Stented	Readily available Short period of anticoagulation	Limited lifespan
Stentless	Readily available Probably better haemodynamics with less outflow tract obstruction Short period of anticoagulation	Limited lifespan More difficult to insert
Homograft	No anticoagulation Improved haemodynamics Long-term outcome uncertain	Not readily available Technical difficulties

Table adapted from Sharpe DAC, Das SR. Heart valve surgery. *Surgery* 2000; **18**: 265–9.

year later. Continued improvements in perioperative care, myocardial protection and, in particular, the development of prosthetic heart valves have improved long-term haemodynamic effects, and provided symptom relief and prolonged survival. The majority of valvular operations involve surgery on the aortic or mitral valve; tricuspid and pulmonary valve surgery is rarely undertaken.

Surgical anatomy

Heart valves function to maintain pressure gradients between cardiac chambers and so ensure unidirectional flow of blood without reflux through the heart. The aortic valve is tricuspid with semilunar leaflets attached to the aortic wall at the annulus with the aortic sinuses being above the base of each leaflet, two of which form the origin or ostium of the coronary arteries. The intrinsic shape of the aortic semilunar valve allows blood to leave the ventricle during systole and prevents its regurgitation during diastole. If disease leads to disruption of the leaflets or the annulus, valve function will be affected.

The mitral valve is bileaflet; the anterior leaflet is larger in area. The leaflets, like those of the aortic valve, are attached to an annulus. The leaflets join at two commissures and are supported by a subvalvular apparatus consisting of chordae tendinae and papillary muscles. The papillary muscles contract in ventricular systole, pulling the cusps towards the atrioventricular orifice and holding blood within the ventricle. The proper functioning of the mitral valve depends on the integrity of the annulus, leaflets, chordae and papillary muscles. If surgical correction is required, emphasis is on the preservation of these structures when possible (Figure 54.9).

Surgical options for heart valve disease

The decision of whether to repair or replace the diseased valve depends on the underlying pathology, the severity of disease, and quality and/or involvement of the surrounding supporting structures. Generally, repair is increasingly favoured when

possible in mitral valve disease, particularly in mitral regurgitation in which it has been shown to have good long-term outcomes. Repair is the operation of choice in tricuspid valve disease, but aortic valve surgery generally involves replacing the diseased valve (Table 54.1).

Important factors in selecting the type of procedure and prosthesis include the age of the patient and the need for anticoagulation. Because of uncertainties about its lifespan, there is debate about when a bioprosthetic valve should be used, with most accepting its use in those over 65 years. The need for anticoagulation may have an impact on choice of valve, particularly in women of child-bearing age, the elderly, the presence of congenital or acquired bleeding diathesis and when there is the need for further major surgery.

Figure 54.9 Four valves of the heart.

Types of prosthetic valves

Mechanical valves

Mechanical valves can be used in any age group to replace any valve (Figure 54.10). They are extremely durable, but the components of the valve are thrombogenic and therefore the patient requires systemic anticoagulation, usually with warfarin. This subjects the patients to a lifetime of blood tests, medication and the constant threat of haemorrhagic (intracerebral, epistaxis, gastrointestinal bleed) or thrombotic (cerebral infarction) complications.

Biological valves

Biological valves include **homograft** (or **allograft**) valves, removed from cadavers; **autografts**, a patient's own valve; and, most commonly, **heterografts** (or **xenografts**) prepared from animal tissues. All share the basic design of three semilunar leaflets with central flow, so decreasing pressure gradients and minimising turbulence (Figure 54.11). Heterograft 'tissue' valves are the most commonly used valves and can be stented with a limited durability of 10–15 years, whereas stentless (or frameless) valves are expected to have less late calcific degeneration, but are more technically difficult to insert.

Prosthetic valve dysfunction and complications

Structural valve failure

Bioprosthetic valves are vulnerable to degenerative changes. Structural failure rates for biological valves, although rare in those over 70 years of age, can reach 60 per cent after 15 years. However, newer biological valve have a reoperative rate of less than 10 per cent at 20 years. Structural failure of a mechanical valve is generally uncommon.

Paravalvular leak

Early-onset paravalvular leaks usually result from technical difficulties at insertion. Late-onset leaks can occur and may be related to an episode of endocarditis or, in the presence of bioprostheses, leaflet degeneration. The leak can cause haemolytic anaemia or haemodynamic compromise and the valve may need replacement.

Figure 54.10 Bileaflet mechanical valve.

Thrombosis and thromboembolism

Thrombus formation on a prosthetic valve remains the most common complication of mechanical and biological valves (Figure 54.12). The risk of thromboembolism is greater with a valve in the mitral position (mechanical or biological) than with one in the aortic position. Improved haemodynamic function lowers the probability of thromboembolism. The incidence of thromboembolism in current mechanical valves is 0.5–3 per cent per patient-year.

Prosthetic valve endocarditis

The incidence of prosthetic valve endocarditis (PVE) is 2–4 per cent. The risk is lifelong and at its greatest in the first 15 weeks after surgery. The incidence of PVE is higher with mechanical and bioprosthetic valves and lowest with homograft and autograft valves. The diagnosis is suspected following symptoms of septicaemia, appearance of a new murmur or a septic embolus. It is confirmed with echocardiography, which may show vegetations and even abscess formation. A high index of suspicion is required and early multiple blood cultures are needed to confirm the diagnosis, identify the infective organism and choose appropriate antibiotic therapy. The most common organisms that can lead to PVE are the *Staphylococcus* species, particularly *Staphylococcus epidermidis* in early PVE and *Staphylococcus aureus* (at least 50 per cent of cases); the *Streptococcus* species, usually *Streptococcus viridans*, but also *Streptococcus pneumoniae*, and less commonly, Gram-negative bacilli, as well as fungal organisms.

The treatment of choice is early aggressive intravenous antibiotic therapy. Serial echocardiography to assess extent of infection into surrounding myocardial tissue, as well as functional assessment of the infected valve, may help in optimising decisions on timing of surgical intervention. The prognosis of PVE remains poor with an overall mortality rate of over 50 per cent.

Postoperative management

Antibiotic prophylaxis

Valve surgery, like all cardiac procedures, requires perioperative and immediate postoperative antibiotic prophylaxis. If prosthetic

Figure 54.11 Porcine heterograft stented valve.

infective endocarditis is to be avoided, further prophylaxis with appropriate antibiotics is required during dental and minor surgical procedures in all patients with prosthetic heart valves.

Anti-thrombotic therapy

All patients with mechanical valves require warfarin, usually started on the second postoperative day. The use of anticoagulation or anti-platelet therapy with biological valves is variable and depends on the patient's underlying rhythm postoperatively.

Mitral valve disease

Approximately one-third of all valve surgery performed in the UK is for mitral valve disease, with increasing emphasis on valve repair as the importance of preserving the mitral valve apparatus has become apparent.

Mitral regurgitation

Any pathological process affecting the mitral valve apparatus may lead to mitral regurgitation. As such, there are many causes of regurgitation and they can be broadly classified into five headings (Summary box 54.9).

Summary box 54.9

Causes of mitral regurgitation and likely pathology

Degenerative

- Mitral valve prolapse
- Floppy valve: degeneration of the leaflets with/without chordal rupture
- Senile calcification: calcified annulus
- Connective tissue disorders (e.g. Marfan syndrome, Ehlers-Danlos syndrome): disruption of mitral valve apparatus

Ischaemic

- Papillary muscle rupture: following myocardial infarction
- Dynamic mitral regurgitation: as a result of transient ischaemia
- Poor left ventricular function: most common 'functional' cause secondary to myocardial ischaemia

Rheumatic

- Previous acute rheumatic fever: stiffened leaflets unable to coapt

Infective

- Endocarditis: leaflet destruction

Adapted from Hall R. Mitral valve disease. *Medicine* 1997; 25: 27.

Pathophysiology

There is an important distinction between acute and chronic mitral regurgitation. The former is usually as a result of ischaemic papillary muscle rupture or following infective endocarditis, whereas the latter is a result of myxomatous degeneration of the leaflets leading to a floppy valve.

In acute mitral regurgitation, the left ventricle ejects blood back into a small poorly compliant left atrium, imposing a sudden volume load on the left atrium during ventricular systole. This leads to an abrupt rise in left atrial pressure followed by a rise in pulmonary venous pressure and pulmonary oedema.

In chronic mitral regurgitation, the process is sufficiently slow to allow compensatory left ventricular dilatation and

Figure 54.12 Thrombus (marked T and illustrated with the arrows) on the moving components of a ball-and-cage valve.

hypertrophy, and dilatation of the left atrium without any significant increase in pressure, so protecting the pulmonary circulation. As the disease advances and left atrial dilatation can no longer cope, left atrial pressure begins to rise, leading to a rise in pulmonary venous pressure and progressive pulmonary congestion, and eventual congestive cardiac failure.

Clinical features

In acute mitral regurgitation, the patient is usually unwell, presenting with clinical and radiological evidence of acute pulmonary oedema and a loud apical pansystolic murmur. Patients with mild chronic mitral regurgitation are usually asymptomatic. With progressive pulmonary congestion and left ventricular failure, the patient develops fatigue, dyspnoea on exertion and orthopnoea. The development of atrial fibrillation with left atrial dilatation is common. The enlarged left ventricle leads to a heaving apical impulse and a pansystolic murmur.

Investigations

- **ECG** may show only left atrial hypertrophy (bifid P waves), left ventricular hypertrophy and atrial fibrillation.
- **Chest radiography.** There may be cardiomegaly with prominent pulmonary vasculature.
- **Echocardiography** is often combined with colour flow Doppler imaging, which shows the severity of the regurgitant jet of mitral regurgitation.
- **Coronary angiography.** To investigate the coronary arteries.

Indications for surgery

Indications for surgery include severe symptoms as assessed by the New York Heart Association (NYHA) functional classification system, a progressive increase in left ventricular volume leading to ventricular dysfunction, uncontrolled endocarditis and severe acute mitral regurgitation (Figure 54.13). Timing of

Figure 54.13 Features and pathophysiology of mitral regurgitation. There is a loud parastolic murmur and the left atrium enlarges. The left ventricle enlarges as a consequence of volume overload.

surgery is crucial, as surgery performed too late in the natural history of the condition does not benefit the patient because of the damage already done.

Mitral stenosis

The most common cause of mitral stenosis remains rheumatic fever (Summary box 54.10), despite the fact that the incidence of overt rheumatic fever in the developed world has decreased. During the healing phase of acute rheumatic fever, the valve leaflets become adherent to each other at their free border so that the commissures become obliterated and the valve orifice narrows. Symptoms from mitral stenosis usually develop more than ten years after the acute attack.

Summary box 54.10

Causes of mitral valve disease

Stenosis

- Rheumatic heart disease (common)
- Calcification of valve or chordae
- Congenital (rare)

Regurgitation

- Rheumatic heart disease
- Valve prolapse
- Left ventricular dilatation or hypertrophy
- Ischaemia
- Bacterial endocarditis

Pathophysiology

Mitral stenosis slows ventricular filling during diastole and the pressure in the left atrium rises to maintain cardiac output. This leads to atrial hypertrophy and dilatation. Pulmonary congestion results from the rise in left atrial pressure but, with time, the lungs are protected against pulmonary oedema by constriction of the pulmonary vessels. However, this adaptive response, along with the passive 'back pressure' generated by the rise in left atrial pressure, leads to pulmonary hypertension. This leads to an increased demand on the right ventricle with eventual right heart failure and tricuspid regurgitation. The development of atrial fibrillation is common and can lead to a significant

reduction in cardiac output. Atrial fibrillation predisposes to thrombi forming in the left atrium, which may embolise.

Clinical features

Patients may remain asymptomatic for years and then present with symptoms when the heart is stressed by an event such as pregnancy, fever or a chest infection, or with the onset of atrial fibrillation. The common symptoms are fatigue and dyspnoea on exertion, which result from the combination of reduced forward flow and increased back pressure. The resulting pulmonary congestion adds to the breathlessness and may produce a cough or haemoptysis. If mitral stenosis is advanced, there may also be a right ventricular heave due to right ventricular hypertrophy in response to pulmonary hypertension. Auscultation reveals an opening snap soon after the second heart sound, as the diseased valve is opened forcibly by the high pressure in the left atrium. The reverse happens when the valve closes and there is a loud 'tapping' first heart sound. In addition, a rumbling mid-diastolic murmur can be heard. The duration of the murmur is related to the severity of the mitral stenosis, increasing in length as the mitral stenosis becomes more severe.

Investigations

- **ECG** may show left atrial enlargement (P-mitrale) or AF. Right axis deviation and other ECG signs of right ventricular hypertrophy (tall QRS complexes in the right ventricular leads V1–3) may also be present.
- **Chest radiography.** There is a small aortic outline and a prominent pulmonary artery. The left atrium is enlarged (sometimes to an enormous degree) along with upper lobe diversion as a result of the raised pulmonary venous pressure. The right ventricle also appears enlarged (Figure 54.14).
- **Echocardiography,** in combination with colour flow Doppler imaging, allows assessment of the flow across the valve and, therefore, the degree of stenosis. Transoesophageal

Figure 54.14 Chest radiograph of long-standing mitral stenosis, showing a massive left atrium.

echocardiography (TOE) may be better at assessing valve morphology in detail and excluding the presence of an atrial clot.

- **Coronary angiography.** To investigate the coronary arteries.

Indications for surgery

Medical management includes the use of anticoagulation in patients with AF or left atrial enlargement. Prophylactic antibiotics for endocarditis should be administered before invasive procedures. Tachyarrhythmias, including fast AF, which may lead to decompensation and cardiac failure, should be avoided. Digoxin is the mainstay of treatment, but other rate-controlling agents are increasingly used. Diuretics may provide some benefit. Surgery is indicated for severe symptoms (NYHA class III or IV), severe mitral stenosis (mitral valve area ≤ 1.5 cm²), or signs of left ventricular dysfunction. These include an ejection fraction of less than 60 per cent and a left ventricular end systolic dimension (LVESD) of more than 45 mm, or systemic emboli. Prognosis is determined by the severity of the stenosis, the size of the atrium, the onset of AF, rising pulmonary artery pressure and the unpredictable risk of embolism from a large, fibrillating atrium (Figure 54.15). Surgical options include mitral valve repair or mitral valve replacement. Old surgical procedures, such as commissurotomy or valvotomy, are rarely currently performed.

Mitral valve operations

Depending on the type of procedure and approach to the mitral valve, a median sternotomy or, occasionally, a right thoracotomy is completed. The mitral valve can be approached directly through the left atrium in the interatrial groove, through the right atrium and then the interatrial septum, or through the left atrial appendage.

Mitral valve repair

The restoration of normal valve function and preservation of the mitral apparatus is preferable to replacement. The functional classification system developed by Carpentier serves as a guideline in valve reconstruction. It allows classification of any mitral insufficiency into one of three groups according to the amplitude of the leaflet motion and provides a useful framework for the

mechanisms of failure of the mitral valve. As a rule, several valvular lesions or abnormalities are involved in a functional abnormality, with specific techniques developed to correct each lesion.

At surgery, the anatomy of the valvular apparatus and sub-valvular structures has to be carefully inspected. In particular, the extent of annular dilatation, leaflet prolapse and chordal dysfunction are assessed. The mitral valve reconstruction is completed using various techniques, including insertion of a prosthetic ring annuloplasty (Figure 54.16), quadrangular resection of the leaflet, use of a sliding plasty, chordal shortening and chordal transposition. There are many different techniques which is an indication that so far, no one technique will address all the issues that can occur during mitral regurgitation. Valve repair, however, offers better preservation of ventricular function and avoids the need for prolonged anticoagulation as well as avoiding valve-related complications, such as PVE or structural dysfunction. Recent advances in surgical techniques and the development of various types of rings lead to increased use of mitral valve repair with excellent results making it the gold standard operation. The operative mortality is 1–3 per cent. Complication-free survival at five years ranges from 80 to 95 per cent.

Mitral valve replacement

When valve repair is not feasible mitral valve replacement is necessary. This usually involves a median sternotomy and access to the left atrium on CPB. The diseased valve is exposed, excised and a suitably sized mechanical or bioprosthetic valve is implanted. The atriotomy is closed following de-airing of the left heart. Intraoperative TOE can be used to assess adequate valve function.

The operative mortality rate for elective mitral valve replacement is approximately 5–6 per cent. This depends largely on the state of the myocardium and the general condition (including age) of the patient. Common serious in-hospital complications include stroke (<4 per cent) and renal failure (3 per cent), although any complication of heart surgery is possible. The longer-term prognosis for patients following mitral valve replacement is generally good in comparison with the natural history of mitral valve disease.

Figure 54.15 Features and pathophysiology of mitral stenosis. The aorta and left ventricle are relatively small because of chronically reduced cardiac output. The atrium is enlarged and may fibrillate, become stagnant and contain a thrombus. The ventricle fills with a turbulent jet that may be detected as a diastolic murmur or a thrill at the apex.

Figure 54.16 Operative view of the completed repair of a mitral valve using a Carpentier-Edwards annuloplasty ring (image courtesy of A Murday FRCS).

Percutaneous mitral valve repair (MitraClip)

The MitraClip® is a device used to reduce mitral valve regurgitation. The method involves suturing of the leaflets of the mitral valve together so that regurgitation into the left atrium is prevented. The valve continues to open through the sides of the suture and therefore blood continues to flow into the left ventricle, although this method is less invasive, associated with rapid recovery, and reduced in-hospital stay. However, it is technically demanding and long-term durability of the results of the device is unknown.

Recent data suggest that Mitraclip may be suitable for a small subset of high-risk or chronic heart failure patients, but not for the vast majority, who are better served by surgery, which leaves them with substantially less mitral regurgitation.

Aortic valve disease

Approximately two-thirds of all valve surgery performed in the UK is for aortic valve disease, which remains common despite a reduction in the incidence of rheumatic fever in the developed world.

Aortic stenosis

Aortic stenosis (AS), as opposed to aortic sclerosis, occurs when a pressure gradient can be demonstrated across the valve. Therefore, the difference is not absolute, as sclerosis can progress to stenosis. The common cause of aortic stenosis in adults is an acquired, degenerative, calcific process that results in immobile aortic valve cusps. Progressive fibrosis and calcification of a congenitally abnormal valve can mimic this degenerative process. The usual congenital abnormality is commissural fusion, leading to a bicuspid aortic valve, which occurs in approximately 1 per cent of the population (Figure 54.17).

Pathophysiology

A pressure gradient develops between the left ventricle and the aorta, with the left ventricle adapting to this systolic pressure overload by an increase in left ventricular wall thickness or hypertrophy. This adaptive response is an attempt to normalise left ventricular wall stress in the face of increased left ventricular systolic pressure, and may maintain a normal cardiac output, prevent left ventricular dilatation and avoid significant symptoms for a number of years. Eventually, myocardial function is affected and, together with insufficient left ventricular hypertrophy to normalise wall stress (load mismatch), ventricular contractility is reduced.

When aortic stenosis is severe and cardiac output is normal, a >50 mmHg gradient between peak systolic left ventricular and aortic pressure exists. As aortic stenosis worsens, cardiac output cannot increase with exertion and eventually becomes insufficient at rest. The reduction in ventricular contractility leads to an irreversible decline in left ventricular function, with dilatation and a rise in left ventricular end-diastolic pressure, to the point of overt left heart failure.

Clinical features

Patients are often asymptomatic until decompensation occurs, typically presenting with dyspnoea and angina, which is due to increased oxygen needs of the hypertrophied left ventricle, reduced coronary filling and inadequate cardiac output during exertion. Patients often describe a feeling of light-headedness or 'near' syncope on effort. Cardiac arrhythmias can also occur.

Auscultation of the heart demonstrates a murmur that is typically harsh, ejection in nature and best heard over the aortic area with radiation to the carotids. With critical aortic stenosis and a fall in cardiac output, the murmur may become quieter. The apex beat may be displaced in late disease along with signs of cardiac congestion (Figure 54.18).

Investigations

- **ECG.** There is left ventricular hypertrophy with tall R waves in the lateral leads and sometimes a 'strain pattern' (S-T depression with inverted T waves in the lateral leads).
- **Chest radiography.** May be normal. Cardiomegaly and pulmonary congestion can be seen in the presence of left ventricular failure. Post-stenotic dilatation of the aorta is occasionally seen (Figure 54.19).

Figure 54.17 (a) Formaldehyde-treated aortic valve (normal tricuspid configuration). (b) Aortic stenosis, different pathologies.

Figure 54.18 Features and pathophysiology of aortic stenosis. Haemodynamic changes in aortic stenosis. Aorta with post-stenotic dilatation.

- **Echocardiography** confirms the diagnosis and, together with colour flow Doppler imaging, allows assessment of the aortic valve gradient, calculation of valve area, and evaluation of left ventricular dimensions and wall thickness.
- **Coronary angiography.** To investigate the coronary arteries.

Indications for surgery

Medical management focuses on the avoidance of systemic hypotension and arterial vasodilatation, which may reduce myocardial perfusion pressure and therefore provoke ischaemia.

The natural history of symptomatic patients with aortic stenosis is dismal, with a ten-year mortality rate of 80–90 per cent. The patient is at risk of sudden death related to the severity of the stenosis. An estimated or actual peak systolic gradient of >6.7 kPa (50 mmHg) with impaired ventricular function on dynamic testing is sufficient indication for aortic valve replacement.

Indications for surgery in asymptomatic patients with severe aortic stenosis are controversial. Most would consider surgery in patients with left ventricular dysfunction, concomitant coronary artery disease, in patients over 60–65 years, severe left ventricular hypertrophy, arrhythmias and silent ischaemia.

Figure 54.19 Chest radiograph in aortic stenosis.

Aortic regurgitation

The causes of aortic regurgitation can be classified according to the speed of development of the regurgitant jet (acute or chronic) or according to the anatomical location of pathology (valve leaflet or aortic wall). The causes of acute aortic regurgitation include infective endocarditis, aortic dissection and trauma. The common causes of chronic aortic regurgitation include degeneration leading to aortic root and/or annular dilatation, congenital bicuspid valve and previous rheumatic fever or endocarditis (Summary box 54.11).

Summary box 54.11

Causes of aortic regurgitation according to predominant anatomical location of pathology

Valve leaflet disease

- Congenital, e.g. bicuspid valve leading to degenerative changes, with ventricular septal defect
- Rheumatic heart disease
- Infective endocarditis

Aortic wall pathology

- Inflammatory, e.g. connective tissue disorders, such as ankylosing spondylitis, systemic lupus erythematosus, rheumatoid arthritis
- Systemic disease, e.g. tertiary syphilis
- Degenerative, e.g. Marfan syndrome, aortic root dissection, senile aortopathy, leading to aortic root/annular dilatation

Adapted from Petch M. Aortic valve disease. *Medicine* 1997; **25**: 31.

Pathophysiology

Acute aortic regurgitation imposes a volume load on the left ventricle because of backflow. It causes a sharp rise in left ventricular end-diastolic pressure, premature closure of the mitral valve and inadequate forward left ventricular filling. The result is sudden haemodynamic deterioration and acute respiratory compromise.

In chronic aortic regurgitation, volume load and left ventricular end-diastolic pressure increase gradually, leading to compensatory left ventricular dilatation and eccentric hypertrophy to maintain adequate cardiac output. Systolic and diastolic function is abnormal, and sudden deterioration can occur.

Clinical features

Long-standing aortic regurgitation is asymptomatic until the left ventricle begins to fail, when exertional dyspnoea may be the only symptom. Angina can also develop. A wide pulse pressure due to a reduction in diastolic pressure and collapsing pulse (waterhammer pulse) are commonly seen. Other manifestations of the wide pulse pressure include visible capillary pulsation of the nail bed (Quincke's sign), pulsatile head bobbing (de Musset's sign), visible arterial pulsation in the neck (Corrigan's sign), a 'pistol shot' sound on auscultating over the femoral artery (Traube's sign) and uvular pulsation (Müller's sign). The apex is displaced laterally, often visible and hyperdynamic or

Ludwig Traube, 1818–1876, physician, The Charité, Berlin, Germany. He worked alongside Rudolf Virchow (1821–1902) and was cofounder of the science of experimental pathology in Germany.

'thrusting' in nature because of the left ventricular hypertrophy. Auscultation reveals a high-pitched early diastolic murmur best heard at the left sternal edge (Figure 54.20).

Investigations

- **ECG.** There is left ventricular hypertrophy and sometimes a 'strain pattern'.
- **Chest radiography.** Cardiomegaly can be seen if the left ventricle is dilating; sometimes, the aortic shadow may also indicate dilatation.
- **Echocardiography.** This allows assessment of the underlying cause and severity of aortic regurgitation and enables the diameter of the aortic root, as well as left ventricular dimensions, to be determined. Colour flow Doppler imaging quantifies the size of the regurgitant jet.
- **Coronary angiography.** To investigate the coronary arteries.

Indications for surgery

Medical therapy with vasodilator drugs for the relief of dyspnoea or angina is designed to improve forward stroke volume and reduce regurgitant volume. However, symptomatic relief does not alter the need for valve surgery.

The indications for surgery are the onset of symptoms of NYHA class III or IV. Minor degrees of aortic regurgitation are well tolerated, but if the left ventricle deteriorates and dilates it may be too late for surgery. An end-diastolic pressure of >70 mmHg, an end-systolic pressure of >50 mmHg, an end systolic dimension of >50 mm and an end-diastolic dimension of >70 mm indicate severe pathology warranting surgical intervention, even in patients with mild symptoms (NYHA class II). Asymptomatic patients with left ventricular dysfunction during exercise should be followed up with regular echocardiography. Aortic valve replacement is recommended if there is progressive left ventricular dilatation or a fall in systolic function occurs (Summary box 54.12).

Aortic valve surgery

Unlike mitral valve surgery, there are few occasions when the aortic valve can be repaired and usually the valve requires replacement. However, in neonates and children, aortic valve repair or valvotomy is well established. Percutaneous aortic balloon valvotomy has a role in children, but appears to offer no benefits in adult aortic valve disease.

Figure 54.20 Haemodynamic consequences of aortic regurgitation. The left ventricle dilates and hypertrophies and there is a diastolic murmur. LAP, left atrial pressure.

Summary box 54.12

Causes of aortic valve disease

Stenosis

- Congenital
- Rheumatic heart disease
- Acquired calcification and fibrosis of valve or chordae tendineae with age

Regurgitation

- Rheumatic heart disease
- Infective endocarditis
- Congenital
- Inflammatory:
 - Systemic lupus erythematosus
 - Rheumatic ankylosing spondylitis
- Dilatation of aortic root:
 - Marfan syndrome
 - Dissection
- Systemic disease:
 - Syphilis
 - Ulcerative colitis

Aortic valve replacement

This is performed through a median sternotomy on CPB. The aorta is cross-clamped and opened proximally to reveal the diseased valve. Cardioplegic solution is infused into the coronary arteries to arrest the heart in diastole. The valve is then excised leaving the annulus *in situ*, but removing as much calcific debris as possible. The annulus is sized and the mechanical or biological valve is then sutured into position at the level of the native annulus and the aortotomy is closed.

The operative mortality rate for elective aortic valve surgery is <5 per cent, but is higher in emergency surgery, in surgery for endocarditis and in older patients.

Major complications include stroke (2 per cent), perioperative myocardial infarction (2 per cent) and heart block requiring a permanent pacemaker (<1 per cent). The major determinant of late survival after aortic valve surgery is preoperative left ventricular function. The five-year survival rate is approximately 75–85 per cent, with the majority of late deaths related to myocardial factors.

Transcatheter aortic-valve implantation

Although aortic valve replacement (AVR) is still the gold standard treatment, a significant number of patients affected by severe AS requiring AVR do not undergo surgery because they are considered too old or too frail for such an invasive procedure, or because they are affected by concomitant comorbidities that noticeably increase the operative risk. In such patients, transcatheter aortic valve implantation is an attractive alternative to standard AVR. Other indications include heavily calcified ascending aorta ('porcelain' aorta) and the presence of a severe congenital thoracic distortion.

There are different approaches for valve implantation; the most commonly used are transapical (antegrade) and transluminal (retrograde).

- **Transapical approach.** The main advantage of performing transapical procedures is that the feasibility does not rely on the absence of a concomitant peripheral vascular disease

Heinrich Irenaeus Quincke, 1842–1922, Professor of Medicine, Kiel, Germany.

Louis Charles Alfred de Musset, 1810–1857, French poet and playwright in whom the sign traditionally was first noticed.

Sir Dominic John Corrigan, 1802–1880, physician, The Charitable Infirmary, Jervis Street, Dublin, Ireland.

Friedrich von Müller, 1858–1941, a physician of Munich, Germany.

or previous aortic surgery. This approach reduces the risk of calcium dislodgement due to the passage of a stiff transluminal device into a diseased aortic arch. In transapical transcatheter aortic-valve implantation (TAVI), the cardiac apex is prepared through a small left anterolateral mini-thoracotomy using a purse-string or a crossing suture reinforced by pledgets and, after the procedure, a chest tube is routinely inserted into the left pleura.

- **Transluminal approach.** This can be carried out via the femoral or subclavian artery. This is a useful technique for patients with previous cardiac surgery; however, the presence of peripheral vascular disease, small vessel diameters, tortuous vessels, aortic disease or previous aortic surgery contraindicates this approach.

Whichever approach is used, a balloon catheter is advanced into the left ventricle over a guidewire and positioned at the opening of the aortic valve. The existing aortic valve is dilated in order to make room for the prosthetic valve. Rapid right ventricular pacing is used to interrupt cardiac output through the existing aortic valve and to reduce movement during implantation. The new valve, mounted on a metal stent, is manipulated into position and is either self-expanding or deployed using balloon inflation. Deployment leads to obliteration of the existing aortic valve.

Complications associated with TAVI include mortality (5–18 per cent at 30 days), mild-to-moderate aortic regurgitation (30–50 per cent), stroke (3–9 per cent), perioperative open conversion (9–12 per cent), vascular complications (10–15 per cent) and atrioventricular block (4–8 per cent). A recent myocardial infarction (less than three months), severe pulmonary dysfunction, and the presence of an apical thrombus are contraindications for transapical TAVI, whereas a left ventricular ejection fraction (LVEF) below or equal to 20 per cent contraindicates all TAVI procedures.

CONGENITAL HEART DISEASE

Introduction

Congenital heart diseases are abnormalities of cardiac structure that are present from birth. Such abnormalities in the development of the heart typically arise in the third to eighth week of gestation. The first operation for congenital heart disease was the ligation of a patent ductus arteriosus (PDA) by Gross in 1938. With the development of neonatal CPB, improved methods of myocardial protection and microsurgical techniques, an increasing number of corrective and palliative operations is possible.

Development of the heart and fetal circulation and circulatory changes at birth

By 12 weeks of fetal life, the primitive vascular tube is fully developed. The fetal circulation differs from that of the adult in that the right and left ventricles pump blood in parallel rather than in series. Such an arrangement allows the heart and head to receive more highly oxygenated blood. In the fetus, this is possible because of the presence of three structural shunts: the ductus venosus, the foramen ovale and the ductus arteriosus (Figure 54.21).

Soon after birth, pulmonary vascular resistance falls because of the action of breathing and the resulting pulmonary

vasodilatation. In addition, within 30 minutes of delivery, the ductus arteriosus constricts in response to an increase in blood oxygen levels. The result is a reversal of the pulmonary–systemic pressure gradient and termination of blood flow from the pulmonary artery into the aorta.

After birth, the act of cutting and tying the umbilical cord stops venous blood flow from the placenta. This lowers the pressure in the inferior vena cava and, with the fall in pulmonary vascular resistance, right atrial pressure falls. The result is closure of the foramen ovale. The abolition of venous return from the placenta also causes the ductus venosus to close.

The closure of the fetal circulatory shunts in the few hours following birth is functional, with complete structural closure typically taking several months. In 20 per cent of adults, the structural closure of the foramen ovale remains incomplete, but is of no cardiovascular significance.

Abnormalities of cardiac structure may arise from the persistence of normal fetal channels (PDA, patent foramen ovale), failure of septation (atrial septal defect, ventricular septal defect, tetralogy of Fallot), stenosis (intracardiac–supravalvular, valvular, infravalvular or extracardiac–coarctation of the aorta), atresia or abnormal connections (transposition of the great arteries, total anomalous venous drainage). Fetal echocardiography is now sufficiently sensitive to detect intracardiac lesions in the second trimester.

Incidence

Congenital heart disease is the most common congenital abnormality in the UK; the incidence of significant cardiac abnormalities is eight cases per 1000 live births. Many

Figure 54.21 Fetal circulation.

Etienne Arthur Louis Fallot, 1850–1911, Professor of Medicine, Marseilles, France.
Jacqueline Ann Noonan, born 1921, paediatric cardiologist, The University of Kentucky College of Medicine, Lexington, KY, USA, described this condition in 1963.

spontaneous abortions or stillbirths have cardiac malformations or chromosomal abnormalities associated with structural heart defects. In neonates and children with congenital heart disease, 15 per cent will have more than one cardiac abnormality and 15 per cent will have another extracardiac abnormality.

Aetiology

There is often no obvious aetiology; most abnormalities appear to be multifactorial with both genetic and environmental influences. There are well-recognised associations (Summary box 54.13).

Summary box 54.13

Recognised associations with congenital heart disease

- Maternal (environmental) factors
 - Infection: rubella
 - Disease: systemic lupus erythematosus, diabetes mellitus
 - Drugs/medications: alcohol abuse, warfarin, phenytoin
- Genetic factors
 - Single gene defects: Marfan, Noonan and Holt–Oram syndromes
 - Chromosomal defects: trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), Turner syndrome
 - Deletions: DiGeorge and Williams syndromes

Diagnosis

Occasionally, an antenatal diagnosis is possible, with severe congenital heart disease detected *in utero* at 16–18 weeks. If an infant is suspected of having a congenital heart disease, a diagnostic evaluation begins with an accurate history from the parents and specific questions about maternal health and drug intake during pregnancy. A detailed family history is important because some defects are familial. Clinical examination may reveal a murmur, evidence of heart failure, failure to thrive and cyanosis. In addition, congenital heart disease can present with hypertension, an arrhythmia, evidence of polycythaemia or a thromboembolic event. Investigation is much the same as for the adult patient and, with fetal echocardiography available, cardiac catheterisation is now avoided whenever possible.

Classification

Congenital heart disease can be broadly classified according to the presence or absence of cyanosis, although the distinction is not always clear-cut. The presence of central cyanosis, blueness of the trunk and mucous membranes, results from levels of deoxygenated haemoglobin of $>3\text{--}5\text{ g/dL}$ in the arterial circulation.

Cyanotic congenital heart diseases make up one-third of cases and are usually more complex, although they do include simple defects. Cyanotic congenital cardiac lesions can involve:

- A right-to-left shunt resulting in decreased pulmonary blood flow. Many of these lesions consist of a septal defect in conjunction with a right-sided obstructive lesion, producing

an obligatory right-to-left shunt. The most common cause of this is tetralogy of Fallot.

- Parallel systemic and pulmonary blood flow rather than in series. If there is no mixing, this is incompatible with life, so typically neonates have a patent foramen ovale that allows some mixing of the two circulations at this level. The most common example of this is transposition of the great vessels (TGV).
- Defects in the connections of the heart in which there is mixing of the systemic and pulmonary flows. An example of such a complex lesion is total anomalous pulmonary venous drainage.

Acyanotic congenital heart diseases represent the other two-thirds of cases and are usually less complex. Such defects result in an increase in the work imposed on the heart because of either:

- A left-to-right shunt with increased pulmonary blood flow, which causes an increase in volume work of the heart. Examples include PDA, atrial septal defect (ASD) and ventricular septal defect (VSD).
- Obstruction of the blood flow across a heart valve on the left side of the heart, such as aortic stenosis, or in the aorta itself, as occurs with coarctation of the aorta, leading to an increase in pressure and work of the heart.

Typically, acyanotic congenital heart disease presents as heart failure in infancy because of pulmonary congestion caused by increased pulmonary blood flow or increased pulmonary venous blood pressure resulting from an obstructive lesion. The common acyanotic cardiac defects can also present as a murmur in infancy or later.

Cyanotic congenital heart disease

Fallot's tetralogy

This is the most common cyanotic congenital heart disease found in children surviving to one year and accounts for about 4–6 per cent of all congenital heart diseases. The four intracardiac lesions originally described (Figure 54.22) were:

- VSD
- overriding aorta
- pulmonary (typically infundibular or subpulmonary) stenosis
- right ventricular hypertrophy.

Clinically, there may be no signs initially but, as pulmonary stenosis progresses, cyanosis typically develops within the first year of life. Squatting is an adaptation by the child to hypoxic spells. This increases systemic vascular resistance and the venous return to the heart and consequently blood is diverted into the pulmonary circulation with increased oxygenation. Lethargy and tiredness are also common. Classically the chest radiograph demonstrates a 'boot-shaped' heart with poorly developed lung vasculature. The diagnosis is confirmed with echocardiography. Surgery to correct the tetralogy can be performed early as a single complete primary repair or later following an initial palliative shunt, which diverts systemic blood into the pulmonary circulation and may be used to improve oxygenation. The results of surgery are good, with a late survival rate at five to ten years following correction of tetralogy of 95 per cent, an operative mortality rate for a repair of between 5 and 10 per cent, and an incidence of reoperation following tetralogy repair of 5–10 per cent.

Mary Clayton Holt, born 1924, cardiologist, The London Hospital for Women and Children, London, UK.

Samuel Oram, 1913–1991, cardiologist, King's College Hospital, London, UK.

Holt and Oram described this condition in a joint paper in 1960.

John Hilton Edwards, 1928–2007, Professor of Genetics, The University of Oxford, UK.

Figure 54.22 Fallot's tetralogy. Four abnormalities that result in insufficiently oxygenated blood being pumped to the body.

Transposition of the great vessels

The condition, first described by Morgagni, is the second most common cyanotic congenital heart disease and is the most common cause of cyanosis from a congenital cardiac defect discovered in the newborn period. TGV results from abnormal development and typically occurs when the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Figure 54.23). The resulting transposition causes the pulmonary and systemic circulations to run in parallel rather than in series, so that oxygenated pulmonary venous blood returns back to the lungs and desaturated systemic venous blood is pumped around the body. The situation is incompatible with life and mixing of the blood must occur through associated shunts such as a patent foramen ovale or associated VSD. The most obvious presentation is severe central cyanosis occurring in the first 48 hours of life. However, if there is a large ASD or VSD, there may be minimal cyanosis initially. Typically, progress is poor and, as pulmonary vascular resistance declines in the neonatal period, high pulmonary flow develops, with cardiac enlargement and left ventricular failure.

The chest radiograph shows pulmonary plethora, with the heart having an 'egg on its side' appearance, with a small pedicle (aorta in front of pulmonary artery). Cardiac catheterisation and echocardiography confirm the diagnosis and delineate the anatomy. Initial palliation is by percutaneous (Rashkind) balloon atrial septostomy or, alternatively, intravenous prostaglandin to keep the ductus open. Definitive repair is usually by the arterial switch procedure, mostly carried out as a two-stage procedure, whereby the pulmonary artery is first banded to 'tone up' the left ventricle. However, the arterial switch procedure without prior pulmonary artery banding is increasingly being carried out in the newborn with TGV and an intact ventricular septum. The long-term results are impressive and it has replaced the atrial switch or baffle (Mustard or Senning) operations.

Figure 54.23 Transposition of the great vessels.

Total anomalous pulmonary venous drainage

Total anomalous pulmonary venous drainage (TAPVD) accounts for only 1–2 per cent of congenital heart disease. In this condition, the pulmonary venous drainage has become disconnected from the left atrium and drains into the systemic venous circulation at some other point (inferior vena cava, superior vena cava, coronary sinus or right atrium). Typically, TAPVD presents after the first week of life with cyanosis that is mild to moderate depending on pulmonary flow. Infants with high pulmonary flow develop cardiac failure, recurrent chest infections, failure to thrive and feeding difficulties. If high pulmonary flow is associated with a large ASD, cyanosis is often minimal and the lesion is tolerated well. If there is additional venous obstruction, cyanosis presents at birth with dyspnoea and pulmonary oedema. Echocardiography and cardiac (pulmonary) angiography are necessary to confirm the diagnosis and establish the location of the anomalous drainage.

The surgical principle is to re-establish the pulmonary venous drainage into the left atrium. The exact operative technique depends on the anatomy and type of TAPVD. The long-term results for survivors of the operation are generally good. Late death following repair is uncommon but, when it occurs, it is often caused by intimal fibroplasia of the pulmonary veins away from the anastomosis.

Eisenmenger's syndrome

Eisenmenger's syndrome is becoming less common as corrective surgery is undertaken increasingly early and fewer patients develop a fixed increase in their pulmonary vascular resistance. It occurs following the reversal of a left-to-right shunt across a previous left-to-right shunt, such as with an ASD, VSD or a patent ductus arteriosus. These congenital anomalies cause an increase in flow and higher right-sided pressures, which lead to compensatory right ventricular hypertrophy and a subsequent rise in pulmonary artery pressure. Increasing pulmonary hypertension leads to equalisation of pressures either side of the shunt but, at some point, the right-sided pressures will exceed those on the left side, resulting in shunt reversal and desaturated blood entering the left side of the circulation. Cyanosis and dyspnoea are the most common clinical features. Closure of the shunt is contraindicated if pulmonary hypertension is irreversible.

because the right-to-left shunt now serves to decompress the pulmonary circulation.

Acyanotic congenital heart disease

Patent ductus arteriosus

The ductus arteriosus, a normal fetal communication, facilitates the transfer of oxygenated blood from the pulmonary artery to the aorta, shunting blood away from the lungs. Normally, functional closure of the ductus occurs within a few hours of birth; it is abnormal if it persists beyond the neonatal period. The ductus closes in response to an increase in peripheral oxygen saturation and a drop in the resistance of the pulmonary circulation as the lungs expand; this causes the ductal tissue to contract through a prostaglandin inhibition mechanism. A cyclooxygenase inhibitor (e.g. indomethacin) may be used therapeutically to close the ductus in the first few weeks of life. In premature babies, the ductus is more likely to remain patent for longer or permanently. In the isolated case of PDA, there is a left-to-right shunt of blood, resulting in a high pulmonary blood flow. Small shunts usually cause few symptoms and signs apart from the continuous machinery murmur in the left second intercostal space. Larger ducts cause cardiac failure and can uncommonly lead to shunt reversal with cyanosis and clubbing. The diagnosis is best confirmed by echocardiography with colour flow Doppler imaging. Cardiac catheterisation is performed only if additional lesions are suspected.

After six months of age, spontaneous closure of a PDA is rare. Most should be closed by preschool age, regardless of the absence of symptoms, if the risks of infective endocarditis, developing left ventricular failure or, rarely, Eisenmenger's syndrome are to be avoided. In the adult, surgical treatment is indicated if there is a persistent left-to-right shunt, even in the presence of pulmonary hypertension. In the premature infant, if medical treatment to close the ductus is unsuccessful, the lesion may be treated by interventional cardiology using an umbrella or coil duct occlusion device inserted percutaneously. If the lesion is very large or the patient very small, surgical closure via a left thoracotomy is preferred. This can be accomplished by either ligation or division of the PDA. The operative mortality rate is low and outcome generally very good.

Coarctation of the aorta

This accounts for 6–7 per cent of congenital heart disease and is defined as a haemodynamically significant narrowing of the aorta, usually in the descending aorta just distal to the left subclavian artery, around the area of the ductus arteriosus (Figure 54.24). The coarctation typically puts a pressure load on the left ventricle, which can ultimately fail. The upper body is well perfused but the lower body, including the kidneys, is poorly perfused, leading to fluid overload, excess renin secretion and acidosis. Coarctation usually affects boys and if it occurs in girls is suggestive of Turner's syndrome.

In the neonatal period, coarctation, often referred to as 'infantile' or preductal coarctation, presents with symptoms of heart failure. The child may appear well in the first few days of life because the coarctation is bypassed by the ductus arteriosus and oxygenated blood reaches the entire systemic circulation. As

the ductus closes, the child becomes progressively more unwell. In adult-type coarctation, which is often juxtaductal or slightly postductal, obstruction is gradual with complications developing in adolescence or early adulthood. Hypertension is a common presenting problem in older children, often upper body hypertension only with development of enormous collateral vessels that may cause rib-notching and flow murmurs over the scapula. Other symptoms include prominent pulsation in the neck, tired legs or intermittent claudication on exercise. Clinical examination of the pulses may demonstrate a radio-femoral delay and a murmur that is continuous and heard best over the thoracic spine or below the left clavicle.

The chest radiograph classically demonstrates rib-notching from the age of six to eight years because of dilated posterior intercostal vessels. The heart is usually of normal size in the older child and shows a classical 'three sign' replacing the typical aortic knuckle. The upper part of the three sign is the dilated left subclavian, the middle part is the narrowing at the coarctation site, and the lower part is the post-stenotic dilatation of the descending aorta. Echocardiography is diagnostic, with cardiac catheterisation performed if other anomalies are present. Infant coarctation typically presents with cardiac failure, often requiring vigorous medical treatment, including the administration of prostaglandin to reopen the ductus and general resuscitation, before corrective surgery. Definitive treatment is usually surgical repair via a left thoracotomy. Coarctation presenting in the child or later typically requires surgical repair, as most patients die before the age of 40 years because of the associated complications. Percutaneous balloon dilatation is an alternative procedure in older children and adults and, in particular, for recoarctation. Without correction, the majority of deaths are caused by heart failure, infective endocarditis, rupture of the aorta or haemorrhagic stroke. The preoperative hypertension may not resolve despite surgical repair.

Figure 54.24 Coarctation of the aorta. Coarctation causes severe obstruction of blood flow in the descending thoracic aorta. The descending aorta and its branches are perfused by collateral channels from the axillary and internal thoracic arteries through the intercostal arteries (arrows).

Victor Eisenmenger, 1864–1932, Austrian physician who first described this condition in 1897, but the term 'Eisenmenger's syndrome' was first introduced in 1958 by **Paul Hamilton Wood** (1907–1962).

Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, Oklahoma City, OK, USA.

Atrial septal defects

An ASD is a defect in the septum between the left and right atria leading to a left-to-right shunt, the significance of which is determined by the size of the defect and the relative compliance of the ventricles. The development of the atrial septum is complex and abnormalities of development lead to three commonly recognised ASDs (Figure 54.25).

The most common type is an ostium secundum ASD. The anomaly is caused by a defect in the floor of the fossa ovalis, resulting in failure of the septum secundum to develop completely and cover the foramen ovale. Secundum defects are usually asymptomatic in childhood, with symptoms developing insidiously, typically presenting in middle age with congestive cardiac failure secondary to pulmonary hypertension or with atrial arrhythmias.

In ostium primum ASD, the anomaly is a form of partial atrioventricular canal defect or endocardial cushion defect. The abnormalities are confined to the atrial septum and are caused by the endocardial cushions failing to develop and so close the ostium primum part of the interatrial septum. The defect is associated with abnormalities of the mitral valve, leading to mitral regurgitation. There is a relatively high incidence of this abnormality in trisomy 21 (Down syndrome). Typically, the primum defect presents earlier than ostium secundum in childhood, with dyspnoea, recurrent chest infections and, if pulmonary hypertension develops, cyanosis.

A sinus venosus ASD is a rare defect and is the result of failure of partition of the pulmonary and systemic venous circulations. These defects are most commonly located high in the atrial septum at the junction of the superior vena cava and the right atrium. They are frequently associated with anomalous pulmonary venous drainage with right superior pulmonary veins draining into the superior vena cava or right atrium directly (Summary box 54.14).

Figure 54.25 Atrial septum viewed from the right. The fossa ovalis is a useful reference point; the most common defect is in this area and is called a fossa ovalis (or ostium secundum) defect. A defect near the atrioventricular junction may be part of the spectrum of atrioventricular septal defects; if the defect is near the entry of the superior vena cava (SVC), it is commonly associated with anomalies of venous drainage into the atria. IVC, inferior vena cava.

Summary box 54.14

ASDs

Common defects

Ostium secundum: fossa ovalis defect (approximately 70 per cent of ASDs)

Ostium primum: atrioventricular septal defect (approximately 20 per cent of ASDs)

Sinus venosus defect: often associated with anomalous pulmonary venous drainage (approximately 10 per cent of ASDs)

Patent foramen ovale: common in isolation, usually no left-to-right shunt (not strictly an ASD)

Rarer defects

Inferior vena cava defects: a low sinus venosus defect and may allow shunting of blood into the left atrium

Coronary sinus septal defect: also known as unroofed coronary sinus with the left superior vena cava draining to the left atrium as part of a more complex lesion

Closure is performed during the first decade of life, even in the absence of symptoms, to avoid late-onset right ventricular failure, endocarditis and paradoxical emboli. In adults, closure is still appropriate for symptomatic improvement and avoidance of complications. The traditional method of closure involves open-heart surgery with CPB and closure of the defect either directly with sutures, as with most secundum defects, or, if the defect is large, using a pericardial or synthetic patch. Closure of small to moderate ASDs using percutaneous catheter-delivered devices in the cardiology catheter laboratory is increasingly common. Primum atrioventricular defect repairs may require additional mitral valve repair. The operative mortality rate for isolated atrioventricular defect repairs is <1 per cent, with an excellent prognosis. Surgical correction of complete atrioventricular canal defects, with closure of the ASD and ventricular septal components and mitral valve repair, is possible with a higher surgical mortality rate.

Ventricular septal defects

A VSD is a defect in the interventricular septum that allows a left-to-right shunting of blood. VSDs account for 20–30 per cent of congenital heart disease and affect approximately 2 in 1000 live births. They may occur in isolation or as part of a more complex set of cardiac abnormalities (e.g. tetralogy of Fallot, complete atrioventricular canal defect). Four major anatomical types of VSD are described, based on the anatomical subsections of the interventricular septum (Summary box 54.15 and Figure 54.26).

The VSD permits a left-to-right shunt at the ventricular level, with subsequent right ventricular volume overload and increased pulmonary blood flow. This may lead to progressive pulmonary oedema and congestive cardiac failure. Persistently elevated pulmonary blood flow and pulmonary vascular resistance also lead to irreversible pulmonary hypertension. They may eventually result in reversal of flow across the defect and Eisenmenger's syndrome. The clinical presentation reflects the magnitude of the left-to-right shunt, which in turn depends on the size of the VSD and the pulmonary and systemic vascular resistances. Small defects may close or cause little systemic disturbance (maladie de Roger); infants are asymptomatic with

Summary box 54.15

Types of VSD

- Perimembranous defect
Also called conoventricular VSD; the most common defect (70–80 per cent), usually located within the membranous septum and may extend to the tricuspid valve annulus or base of the aortic valve
- Muscular defect
Also called trabecular VSD; occurs in 10 per cent of cases and is located within the membranous septum and often multiple
- Atrioventricular defect
Also called atrioventricular canal-type defect; occurs in 5 per cent of cases and is located in the atrioventricular canal beneath the tricuspid valve
- Subarterial defect
Also called infundibular or subarterial VSD; occurs in 5–10 per cent of cases and lies within the conal septum immediately subaortic

Figure 54.26 Ventricular septum viewed from the right, showing the characteristic sites of ventricular septal defects.

normal development. In the first five years, up to 30–50 per cent of VSDs close spontaneously. Clinically, a loud pansystolic murmur can be detected at the left sternal border because of high pressure flow between the ventricles. Large defects typically present with congestive cardiac failure in the first two months of life. Because of the size of the VSD, ventricular pressures are equalised and often only a soft systolic murmur is detected. If left untreated, pulmonary hypertensive changes start from about one year of age. Eisenmenger's syndrome, secondary to shunt reversal in such cases, may become evident in the second decade of life.

Echocardiography confirms the diagnosis and can estimate the degree of shunting across the defect. Cardiac catheterisation can quantify the various pressures within the cardiac chambers and so assess the degree of pulmonary hypertension, as well as demonstrating a step up in oxygen saturation between left and right ventricles. Generally, surgical closure is indicated for large defects, when there is failure to respond to medical therapy, for left-to-right shunts of $>2:1$, when there are signs of increasing pulmonary vascular resistance and in the presence of complications of VSD. These include: (1) aortic regurgitation, which occurs in about 5 per cent of defects; (2) infundibular stenosis, which tends to be progressive and leads to shunt reversal; and (3) infective endocarditis, often presenting with pneumonia or

pleurisy as the infected 'emboli' in a VSD with a typical left-to-right shunt flows into the pulmonary circulation.

THE THORACIC AORTA

The most common pathology affecting the thoracic aorta is aneurysm formation or dissection.

Thoracic aortic aneurysms

A true aneurysm is a localised dilatation of a blood vessel involving all layers of the vessel, whereas a false aneurysm has compressed supporting tissue as its wall and is usually the result of a defect in the vessel intima (from trauma, dissection or previous surgery). Aneurysms are described as fusiform when the whole circumference is affected or saccular when only part of the circumference is involved.

Aortic aneurysms can develop anywhere along its length, but thoracic aortic aneurysms, including those that extend into the upper abdomen (thoracoabdominal aneurysms), account for 25 per cent, typically occurring in men in the fifth to seventh decade or younger in those with connective tissue disorders.

Aetiology

The most common aetiology is atherosclerosis, but connective tissue disorders account for many aneurysms in the aortic root and ascending aorta now that tertiary syphilis is rare. Marfan syndrome is associated with cystic medial degeneration involving the vessel wall and causes widening of the proximal aorta and aortic root, leading to aortic valve insufficiency. Other disorders associated with aneurysm formation and dissection include Ehlers–Danlos syndrome and osteogenesis imperfecta.

Trauma, typically following blunt chest injury, can lead to aneurysm formation, usually involving the descending aorta. However, these are usually false aneurysms containing haematoma from injury to the aortic vessel wall.

Clinical features

Many aneurysms are asymptomatic and are discovered incidentally on routine chest x-rays. Others present as a space-occupying lesion in the thorax with pain caused by pressure on adjacent structures (vertebra), hoarseness (left recurrent laryngeal nerve), dysphagia (oesophagus) and respiratory symptoms (left main bronchus). Aortic root aneurysms may lead to dilatation of the aortic root annulus and aortic regurgitation.

Rupture can lead to cardiac tamponade or haemorrhage into the left pleural space, leading to dyspnoea and, if the tracheobronchial airway or oesophagus is involved, haemoptysis or haematemesis, respectively.

Investigations

The diagnosis is confirmed by CT or MRI. Arteriography is not necessary for diagnosis but is often required to demonstrate the relation of the arch vessels to the aneurysm.

Indications for surgery

Without treatment, the aneurysm is likely to expand and ultimately rupture. Important factors to consider when planning treatment are age, comorbidity and coexisting coronary disease.

Edvard Ehlers, 1863–1937, Professor of Clinical Dermatology, Copenhagen Denmark.
Henri Alexandre Danlos, 1844–1912, dermatologist, Hôpital St Louis, Paris, France, gave his account of this condition in 1908.

In ascending aneurysms, the presence of progressive aortic valve insufficiency is an important indication for surgery. Other indications in this group, including Marfan-related aneurysms, are a diameter of 5–6 cm and the presence of symptoms. In descending aneurysms, indications for surgery include symptoms, acute enlargement and a diameter of approximately 6 cm.

Surgical options

The approach adopted for surgical treatment depends on the location of the aneurysm, but typically involves a median sternotomy, CPB and cooling the patient to 18°C before cross-clamping the aorta above the aneurysm (Figure 54.27). If the aortic root is involved, the aorta, together with its annulus and valve, is resected and a composite graft is sutured to the aortic root. The circulation is arrested and, after removal of the aortic cross-clamp, the distal anastomosis is completed. The coronary ostia require reimplantation into the graft (Bentall's operation). If the ascending aorta is involved, it is resected and replaced with a tube graft. For aortic arch aneurysms, surgery on this section of the aorta is a formidable undertaking because the cerebral and subclavian vessels have to be anastomosed to the graft, either separately or en bloc. Typically, it involves a period of circulatory arrest and some form of cerebral protection. Excision of a descending aortic aneurysm is with graft replacement under CPB with exposure via a left thoracotomy or with a heparin-bonded shunt. Increasingly, thoracic aneurysms at the aortic arch or more distal are repaired using a percutaneous approach via the femoral artery with insertion of an endovascular stent under radiological guidance.

Surgical outcome

The operative mortality rate is variable depending on the location and type of repair required but electively is between 5 and 15 per cent. An emergency repair has a considerably higher operative mortality rate. Long-term survival depends on underlying pathology but, for ascending aneurysm repairs, the five-year survival rate is approximately 65 per cent. The major complications of descending aneurysm repairs include paraplegia, renal failure and ventricular dysfunction.

Aortic dissection

This occurs when there is a defect or flap in the intima of the aorta, resulting in blood tracking into the aortic tissues splitting

Figure 54.27 A large thoracic aortic aneurysm.

the medial layer and creating a false lumen. It most commonly occurs in the ascending aorta or less often just distal to the left subclavian artery. It is also more common in men, typically those aged 50–70 years, and in Afro-Caribbeans.

Aetiology

It usually occurs as a spontaneous or sporadic event, although very often a history of hypertension is noted. Other important associations include Marfan syndrome and pregnancy (Summary box 54.16).

Summary box 54.16

Predisposing factors for aortic dissection

- Age
- Hypertension
- Marfan syndrome
- Pregnancy
- Other connective tissue disorders, for example Ehlers–Danlos syndrome, giant cell arteritis, systemic lupus erythematosus
- Coarctation of the aorta
- Turner or Noonan syndromes
- Aortotomy site

Clinical features

The presentation is often a tearing intrascapular pain not unlike the pain of myocardial ischaemia, and it may be difficult to distinguish between the two. The extent of arterial dissection may produce widespread symptoms and signs.

The dissection can extend distally down the aorta to involve:

- the renal arteries (renal pain and renal failure);
- the mesenteric arteries (abdominal pain and bowel ischaemia);
- the spinal arteries (paraplegia);
- the iliac arteries (leg pain, pallor, loss or reduced pulses and limb ischaemia).

The dissection may track proximally to involve:

- the head and neck vessels (symptoms and signs of a stroke or transient ischaemic attack);
- the coronary vessels (myocardial infarction);
- the aortic root (aortic regurgitation).

The aneurysm may rupture back into the lumen or externally into the pericardium (cardiac tamponade) or mediastinum (left haemothorax).

Classification

There are two classifications, both of which are limited in their application but widely used. The DeBakey classification is based on the pattern of dissection, whereas the Stanford classification is based on whether the ascending aorta is involved (Figure 54.28).

Investigations

The diagnosis is suspected when chest radiography demonstrates a widened mediastinum, often associated with fluid in the left costophrenic angle. Diagnosis is confirmed by whatever method is most readily at hand and includes echocardiography, ideally TOE, CT of the thorax or MRI (Figure 54.29). Traditionally,

Figure 54.28 Stanford classification of aortic dissections according to whether the ascending aorta is involved (type A) or not (type B). This is simpler than the DeBakey classification (types I, II and III).

aortography was the 'gold standard' technique and it still provides excellent information before surgery but, increasingly, advanced three-dimensional CT angiography and MRI are used when available.

Management

In the emergency situation, before further imaging, blood pressure (which is usually high at presentation) should be brought under control to prevent extension of the dissection.

Surgical options

Type A (or type I and II) dissections

Those involving the ascending aorta usually require surgical intervention. The chest is opened through a median sternotomy and CPB is started with core cooling down to 18°C. The aorta is cross-clamped as high as possible and opened. Cardioplegia solution is infused into the coronary ostia to arrest the heart in diastole. If the intimal tear is present and localised, the ascending aorta is excised with the tear and replaced with a synthetic graft. The distal anastomosis is performed with circulatory arrest. Recently, there have been attempts to carry out endovascular stenting of type A dissection with variable degrees of success.

Type B (or type III) dissections

Initially, these are best managed medically with antihypertensive drugs. Surgery is indicated if the pain increases (signalling impending rupture), the aneurysm is expanding on serial chest radiographs or complications, such as organ, limb or neurological symptoms, develop. The operation may be performed with a heparin-bonded shunt or under CPB. There is a real risk of paraplegia from this operation, which should be mentioned specifically to the patient before operation. Use of percutaneously placed endovascular stents is likely to increase in the future, although currently its role in the acute setting remains to be established. There has been a shift in the surgical management of type B dissection towards endovascular stenting which can be a part of a hybrid operation including surgical replacement of parts of the aorta, such as the arch.

Outcomes

If dissection is untreated, the mortality rate is 50 per cent within 48 hours and 75 per cent within 1–2 weeks. Almost all patients with type A dissections will die if not operated on, whereas patients with type B dissections have a better prognosis. The

Figure 54.29 Computed tomography scan showing acute dissection of the descending thoracic aorta. F, false lumen; T, true lumen.

surgical mortality rate is variable but is around 15 per cent for proximal aortic dissection. The overall survival rate for patients leaving hospital, regardless of the type of dissection, is around 80 per cent at five years and 40 per cent at ten years.

PERICARDIAL DISEASE

There is a fibrous envelope covering the heart and separating it from the mediastinal structures. This fibrous structure includes a parietal layer and allows the heart to move with each beat. It is not essential for life because it can be left wide open after cardiac surgery without any ill-effects; however, there are a number of conditions affecting the pericardium that may present to the surgeon.

Pericardial effusion

There is a continuous production and resorption of pericardial fluid. If a disease process disturbs this balance, a pericardial effusion may develop. If the pressure exceeds the pressure in the atria, compression will occur, venous return will fall and the circulation will be compromised. This state of affairs is called 'tamponade'. A gradual build up of fluid (e.g. malignant infiltration) may be well tolerated for a long period before tamponade occurs, and the pericardial cavity may contain 2 litres of fluid. Acute tamponade (from penetrating trauma, during coronary angiography or postoperatively) may occur in minutes with small volumes of blood. The clinical features are low blood pressure with a raised jugular venous pressure and paradoxical pulse. Kussmaul's sign is a characteristic pattern that is seen when the jugular venous pressure rises with inspiration as a result of the impaired venous return to the heart.

Emergency treatment of pericardial tamponade is aspiration of the pericardial space. A wide-bore needle is inserted under local anaesthesia to the left of the xiphisternum, between the angle of the xiphisternum and the ribcage (Figure 54.30). The needle is advanced towards the tip of the scapula into the pericardial space. An ECG electrode attached to the needle will indicate when the heart has been touched. This will relieve

Figure 54.30 (a) Pericardial aspiration through the subxiphoid region. (b) Site of needle insertion for pericardial aspiration.

the situation temporarily until the cause of the tamponade is established. Penetrating wounds of the heart usually require exploration through a median sternotomy. Emergency room thoracotomy is rarely required. Chronic tamponade is usually a result of malignant infiltration of the pericardium (usually secondary carcinoma from breast or bronchus) or, very occasionally, uraemia or connective tissue disease. Treatment sometimes requires a pericardial window between the pericardial space and the pleural or peritoneal space.

Pericarditis

Infection and inflammation may also affect the pericardium. Acute pericarditis usually occurs following a viral illness. Treatment is with non-steroidal anti-inflammatory drugs and bed rest (in case there is an underlying myocarditis). Acute purulent pericarditis is uncommon, but requires urgent drainage and intravenous antibiotics with attention to the underlying cause.

Chronic pericarditis is an uncommon condition in which the pericardium becomes thickened and non-compliant. The heart cannot move freely and the stroke volume is reduced by the constrictive process. The central venous pressure is raised and the liver becomes congested. Peripheral oedema and ascites are also a feature. Treatment is aimed at relieving the constriction.

MANAGEMENT OF CARDIAC ARREST AFTER CARDIAC SURGERY

Introduction

The incidence of cardiac arrest after cardiac surgery is around 0.7–2.9 per cent with 17–79 per cent survival rates. Ventricular fibrillation (VF), tamponade and major bleeding account for most arrests. Multiple variables may dictate differences in the management of cardiac arrest after cardiac surgery when compared to other situations. Therefore, EACTS published guidelines for resuscitation of cardiac arrest post-cardiac surgery which are summarised below.

Cardiac arrest with 'non-shockable' rhythm

Cardiac surgical patients who have a non-VF/VT (ventricular tachycardia) arrest may have tamponade, tension pneumothorax, or severe hypovolaemia. Prompt treatment is associated

with an excellent outcome. Resternotomy should be performed promptly if connecting the pacemaker and administering atropine fail to resolve the arrest especially if prolonged period of cardiopulmonary resuscitation (CPR) is needed which will be better performed by internal massage.

Emergency resternotomy for ventricular fibrillation or pulseless ventricular tachycardia

A precordial thump may be performed if within 10 s of the onset of VF or pulseless VT, however, this should not delay cardioversion by defibrillation. In VF or pulseless VT, emergency resternotomy should be performed after three failed attempts at defibrillation.

Emergency resternotomy

After the identification of cardiac arrest, basic life support according to the ALS (advanced life support) guidelines should be initiated while preparing for emergency resternotomy. Emergency resternotomy may be required in 0.8–2.7 per cent of all patients undergoing cardiac surgery. Emergency resternotomy is a multi-practitioner procedure, which should be rapidly performed with full aseptic technique.

Preparation for emergency resternotomy

- Don a gown and gloves in a sterile fashion.
- Apply the thoracic drape ensuring that the whole bed is covered. (If an all-in-one sterile drape is used, then there is no need to prepare the skin with antiseptic.)
- Use the scalpel to cut the sternotomy incision, including all sutures deeply down to the sternal wires.
- Cut all the sternal wires with the wire cutters. The sternal edges will separate a little which may relieve tamponade.
- Use suction to clear excessive blood or clot.
- Place the retractor between the sternal edges and open the sternum.
- If cardiac output is restored, wait for expert assistance. If there is no cardiac output, carefully identify the position of any grafts and then perform internal cardiac massage and internal defibrillation if required.

Internal cardiac massage

This is a potentially dangerous procedure. Risks include avulsion of a bypass graft, with the left internal mammary artery being at particular risk, and right ventricular rupture especially if it is thin or distended. Therefore, it is important to carefully remove any clot and identify structures at risk, such as grafts, before placing hands around the heart.

There are several methods of internal massage, however, the two-hand technique is the safest.

Two-hand technique

The heart should be inspected to locate the internal mammary and any other grafts if present followed by removing any blood clots. The right hand is passed over the apex of the heart and then advanced round the back of the heart, palm up and hand flat. The left hand is then placed flat onto the anterior surface of the heart and the two hands squeezed together at a rate of 100 per minute. Flat palms and straight fingers are important to avoid an unequal distribution of pressure onto the heart, thereby minimising the chance of trauma. If there is a mitral valve

replacement or repair, care should be taken not to lift the apex by the right hand, as this can cause a posterior ventricular rupture.

LEARNING OBJECTIVES

To understand:

- The anatomy and physiology of the thorax
- Investigation of chest pathology
- The role of surgery in pleural disease
- The assessment of patients requiring lung surgery
- Surgical oncology as applied to chest surgery

INTRODUCTION

Anatomical development of the lungs

The lungs are derived from an outpouching of the primitive foregut during the fourth week of intrauterine life. This bud becomes a two-lobed structure, the ends of which ultimately become the lungs. The lobar arrangement is defined early and is fairly constant but anomalies of fissures and segments leading to anatomical variation in the adult are common.

The primitive lungs drain into the cardinal veins, which ultimately become the pulmonary veins draining into the left atrium. Variability in venous drainage is very common and is usually of little functional significance. At the most severe end of the spectrum is total anomalous drainage, which presents in early infant life because oxygenated blood is all directed back to the right heart.

Anatomy of the lungs

The left lung is divided by the oblique fissure, which lies nearer vertical than horizontal, so the upper and lower lobes could also be called anterior and posterior. On the right, the equivalent of the left upper lobe is further divided to give the middle lobe. Each lobe is composed of segments, with anatomically defined and named bronchial, pulmonary arterial and venous connections (Figure 55.1).

The right main bronchus (RMB) is shorter, wider and nearly vertical compared with the left main bronchus (LMB). As a consequence, inhaled foreign bodies are more likely to enter the right main bronchus than the left (Figure 55.2). The trachea and bronchi have a systemic arterial blood supply delivered by the bronchial arteries, which arise directly from the nearby thoracic aorta.

Lymphatic drainage tends to follow the bronchi. Lymph nodes are both named and identified by numbered 'stations', which are of importance in staging of lung cancer (Figure 55.3).

Mechanics of breathing

The intercostal muscles contract, causing the ribs to move upwards and outwards, thereby increasing the transverse and

Figure 55.1 The lobar and segmental divisions of the lungs, right lung above and left lung below as if viewed from the side.

anteroposterior dimensions of the chest wall. The diaphragm contracts simultaneously and flattens, increasing the vertical dimension of the chest cavity. As the volume increases, the intrathoracic pressure falls and air flows in until the alveolar pressure is the same as the atmospheric pressure. The only force used in normal expiration is the elastic recoil of the lung.

Coughing to clear sputum is an essential part of recovery from surgery. In a vigorous cough, probably the only muscle in the body that is relaxed is the diaphragm; as the abdomen and chest wall muscles contract, the limbs are braced and the sphincters are tightened. When the intrathoracic and abdominal pressure is built up, the glottis is opened and the diaphragm is forced up

Figure 55.2 Surgical anatomy of the bronchial tree. To surgically remove the right lower lobe and conserve the middle lobe, the surgeon must be prepared to dissect and separately divide the apical bronchial segment (red line).

Figure 55.3 Lymph node stations related to the bronchial tree are particularly important in the staging of lung cancer, with N1 nodes (10–14) and N2 nodes (2–9) shown.

as a piston, or like the plunger of a syringe, to expel air at high velocity.

Investigation of the respiratory system

Any patient undergoing general anaesthesia requires some assessment of respiratory function. This may be a clinical appraisal of fitness but more detail is necessary for patients who are undergoing lung resection.

Pulmonary function tests

Pulmonary function tests (PFTs) are useful in determining the functional capacity of the patient and the severity of pulmonary disease, and in predicting the response to various treatments. The tests range from simple clinic or bedside measurements to those only available in specialist centres. Spirometry is the most commonly performed PFT and measures specifically the amount (volume) and/or speed (flow rate) of air that can be inhaled or exhaled. It is reported in both absolute values and as a predicted percentage of normal. Normal values vary, depending on gender, race, age and height. The most common parameters measured in spirometry are defined below and illustrated (Figure 55.4).

Peak expiratory flow rate

Peak expiratory flow rate (PEFR) is measured by a Wright peak flow meter or a peak flow gauge. This is the maximum airflow

velocity achieved during an expiration delivered with maximal force from the total lung capacity. It is a reliable and reproducible test but has the disadvantage of being effort dependent, and it may therefore be affected by abdominal or thoracic wound pain. PEFR measurements are often used in managing asthma, but there are many other causes of low PEFR, such as a problem with large airway patency.

Forced expiratory volume in 1 second

The forced expiratory volume in 1 s (FEV_1) is the amount of air forcibly expired in 1 s. It is low in obstructive lung disease and may be normal in patients with poor gas exchange.

Forced vital capacity

The forced vital capacity (FVC) is the volume of air forcibly displaced following maximal inspiration to maximal expiration. The FEV_1 and the FVC can be measured using a Vitalograph and a ratio (FEV_1/FVC) can be calculated (Figure 55.4). A low ratio indicates obstruction and the test should be repeated after bronchodilators. A normal ratio (FVC and FEV_1 reduced to the same extent) indicates a restrictive pathology.

There are two physiological categories of lung disease: obstructive and restrictive (Table 55.1). In obstructive conditions, such as asthma or emphysema, the flow of air in and out of the lungs is impaired. In restrictive disease, such as lung fibrosis, the lungs have lost size or elasticity, becoming 'stiff' so that they do not fill or expand properly.

Table 55.1 Spirometry values in obstructive and restrictive lung diseases.

	Obstructive pattern	Restrictive pattern
PEFR	↓↓	Normal or ↓
FEV_1	↓↓	Normal or ↓
FVC	Normal or ↓	↓↓
FEV_1/FVC	<70	>80

FEV_1 , forced expiratory volume in 1 s; FVC, forced vital capacity; PEFR, peak expiratory flow rate.

Diffusion capacity

The diffusion capacity (DLCO) is a measurement of the lung's ability to transfer gases and is often referred to as the 'transfer factor'. It cannot be performed at the bedside, requires the patient's current haemoglobin level and is a test of the integrity of the lung's alveolar-capillary surface area for gas exchange. In lung diseases that damage the alveolar walls, such as emphysema, or thicken the alveolar membrane, such as lung fibrosis, it may be reduced.

Oxygen saturation

Oxygen saturation (SpO_2) refers to the degree of oxygen molecules (O_2) carried in the blood attached to haemoglobin (Hb) molecules. It is a measure of how much oxygen the blood is carrying as a percentage of the maximum it could carry. The common method of monitoring the oxygenation of a patient's haemoglobin is through a pulse oximeter.

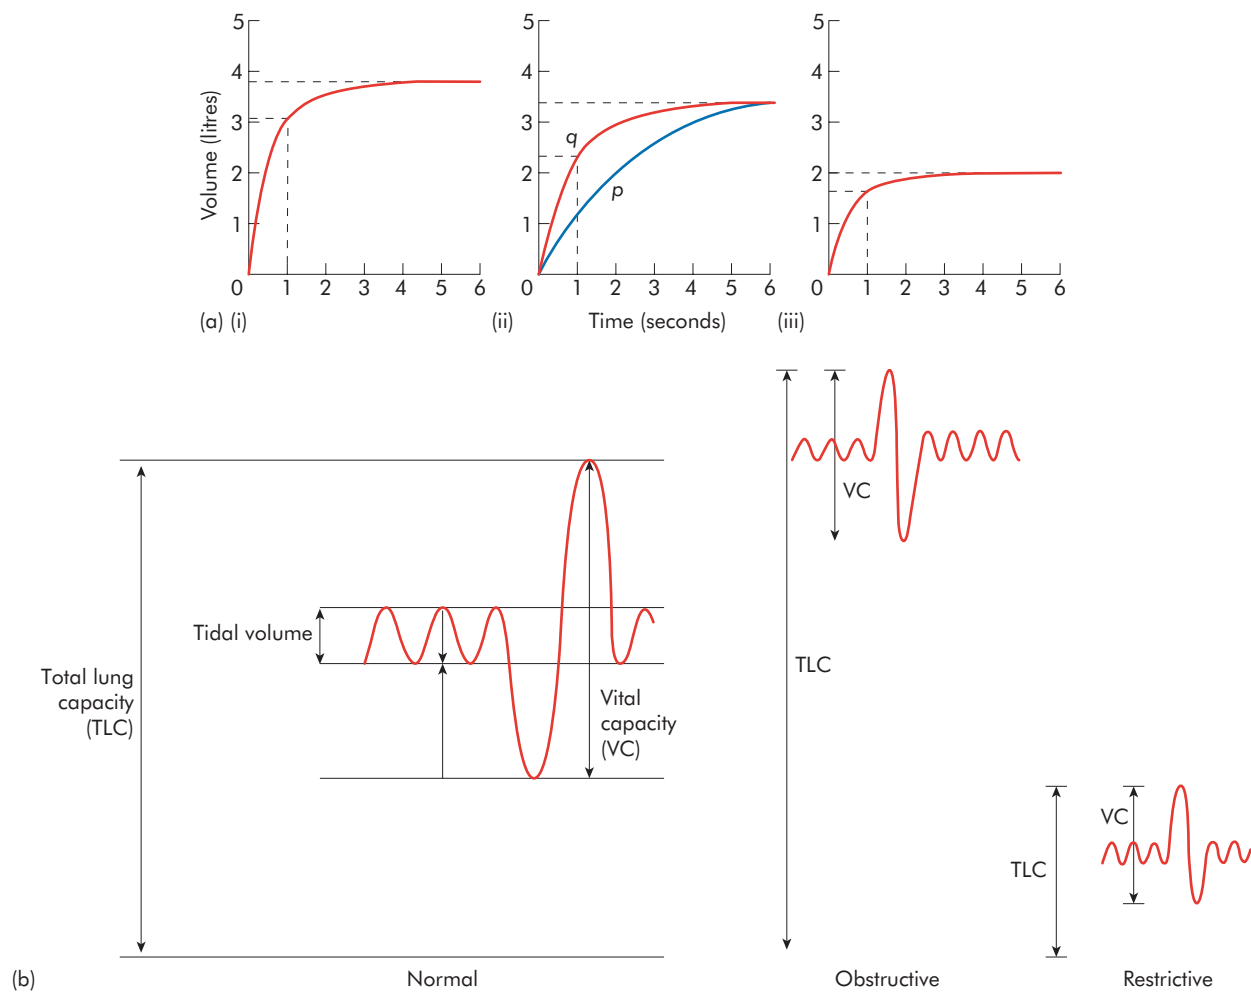

Figure 55.4 Spirometry. (a) Spirogram drawings obtained from a Vitalograph: (i) normal forced expiratory volume in 1 s (FEV_1) 3.1 litres, forced vital capacity (FVC) 3.8 litres, FEV_1/FVC 82 per cent; (ii) obstructive defect, reversible asthma, p before a bronchodilator, FEV_1 1.4 litres, FVC 3.5 litres, FEV_1/FVC 40 per cent; q after a bronchodilator, FEV_1 2.5 litres, FVC 3.5 litres, FEV_1/FVC 71 per cent; (iii) restrictive defect, fibrosing alveolitis, FEV_1 1.8 litres, FVC 2.0 litres, FEV_1/FVC 90 per cent. No change with bronchodilators. (b) Changes in lung volume in obstructive and restrictive lung disease. (Reproduced from Gray HH. Pulmonary embolism. *Medicine International* 1993; **21**: 477, by kind permission of the Medicine Group (Journals) Ltd.)

Blood gases

SpO_2 measured non-invasively with a pulse oximeter measures only oxygenation, not ventilation and provides no information regarding a patient's carbon dioxide or bicarbonate levels, blood pH, base deficit. This requires arterial blood sampling or 'blood gases' (Table 55.2).

Table 55.2 Arterial blood gases 'normal values'.

pH	7.35–7.45
$PaCO_2$	4.5–6 kPa (35–50 mmHg)
PaO_2	11–14 kPa (83–105 mmHg)
Standard bicarbonate	22–28 mmol/L
Anion gap	10–16 mmol/L
Chloride	98–107 mmol/L

The pleura

The key to many aspects of practical chest surgery is an understanding of the pleura and of the mechanics of breathing. Management of the essentially healthy pleural space is logical and simple and needs minimal technology. On the other hand, when pleural disease is advanced, for example when there is gross pleural sepsis surrounding a leaking and trapped lung, management is difficult and the patient may require prolonged care with repeated interventions.

The physiology of pleural fluid

The turnover of fluid in the human pleural space is about 1–2 litres in 24 hours, with only 5–10 mL of fluid present at any one time as a film, about 20 μm thick, between the visceral and parietal pleura.

The mechanisms and equations given are simplifications, but serve to explain the clinical conditions encountered. The fluid is produced from the capillaries of the parietal pleura as a

transudate, according to the Starling capillary loop pressures. However, there is a further negative force in the pleura. The elastic content of the lung causes it to recoil and collapse if not held open by the negative pressure in the pleura. This elastic recoil exerts about 4 mmHg negative pressure and favours accumulation of fluid. The secreting forces add up to about 11 mmHg in health. Pleural fluid is mainly reabsorbed (about 90 per cent) by the visceral pleura, whose capillaries are part of the pulmonary circulation. The principal force in absorption of pleural fluid is oncotic pressure (approximately 25 mmHg) less the difference in mean capillary hydrostatic pressure of the pulmonary capillary (8 mmHg). Thus, the overall absorbing pressure is $25 - 8 = 17$ mmHg, producing a net drying effect ($17 - 11$) of about 6 mmHg (Figure 55.5).

Gas in the pleural space

There is normally no free gas in the pleural space because the same physiological mechanism that absorbs air from a pneumothorax prevents any gas accumulating.

The partial pressures (water as saturated vapour pressure) of the gases in venous/end-capillary blood are:

PO_2	40 mmHg	5.3 kPa
PCO_2	46 mmHg	6.1 kPa
PN_2	573 mmHg	76.4 kPa
PH_2O	47 mmHg	6.3 kPa

These partial pressures add up to less than atmospheric pressure (760 mmHg). Free gas is therefore absorbed into the blood and lost to the atmosphere through the lungs, with the gases moving in relation to their solubility (carbon dioxide quickest and nitrogen slowest) and relative concentrations in the pleural space and the blood. This does not favour nitrogen, which constitutes about 80 per cent of atmospheric air. Breathing oxygen accelerates nitrogen removal by reducing the content of nitrogen in the blood and increasing the gradient for its absorption. Nitrous oxide anaesthesia is dangerous in the presence of a pneumothorax; nitrous oxide is very soluble and, although not normally present in the pleural space, it will be rapidly transported into the space if the patient is given nitrous oxide to breathe.

PLEURAL DISEASE

Pneumothorax

Pneumothorax is the presence of air outside the lung, within the pleural space. It must be distinguished from bullae or air cysts within the lung. Bullae can be the cause of an air leak from the lung and can therefore coexist with pneumothorax.

Spontaneous pneumothorax occurs when the visceral pleura ruptures without an external traumatic or iatrogenic cause. They are divided into primary spontaneous pneumothorax (PSP) and secondary spontaneous pneumothorax (SSP). Pneumothoraces can also occur following trauma or be caused by iatrogenic injury, such as insertion of a central line. Tension pneumothorax is when (independent of aetiology) there is a build up of positive pressure within the hemithorax, to the extent that the lung is completely collapsed, the diaphragm is flattened and the mediastinum is distorted and, eventually, the venous return to the heart is compromised. Any pleural breach is inherently

Produced at a rate of:

0.6 ml kg⁻¹ per hour
or 1000 ml
per day

and reabsorbed:

80–90% into
pulmonary capillaries
10–20% (plus protein)
into lymphatics

(a)

(b)

valve-like because air will find its way out through the alveoli but cannot be drawn back in because the lung tissue collapses around the hole in the pleura. Patients being mechanically ventilated following trauma are at particular risk.

Surgical emphysema is the presence of air in the tissues. It requires a breach of an air-containing viscus in communication with soft tissues, and the generation of positive pressure to push the air along tissue planes. The most serious cause is a ruptured oesophagus. Mediastinal surgical emphysema can also occur with asthma or barotrauma from positive pressure ventilation. A poorly managed chest drain with intermittent build up of pressure allows air to track into the chest wall through the point where the drain breaches the parietal pleura.

Primary spontaneous pneumothorax

This is a common disease characteristically seen in young people from their mid-teens to late twenties. About 75 per cent of cases are in young men, who tend to be tall, and the condition runs in families. It is due to leaks from small blebs, vesicles or bullae, which may become pedunculated, typically at the apex of the upper lobe or on the upper border of the lower or middle lobes.

Secondary spontaneous pneumothorax

This occurs when the visceral pleura leaks as part of an underlying lung disease; any disease that involves the pleura may cause pneumothorax, including tuberculosis, any degenerative or cavitating lung disease and necrotising tumours. As such it tends to occur in older patients, often with a history of underlying lung disease, such as emphysema. The pneumothorax may be less well tolerated.

Usually, pneumothorax presents with sharp pleuritic pain and breathlessness. The pleura is exquisitely sensitive and the movement of the lung on and off the parietal pleura causes severe discomfort. As a result, it is mild cases that are more painful, whereas complete collapse is usually painless but causes more breathlessness. Bleeding and tension pneumothorax can occur. They are usually self-limiting; careful observation is wiser than too-ready resort to a chest drain. If the patient is not in respiratory distress or hypoxic, there is no urgency. Tension pneumothorax should be immediately relieved by inserting a cannula into the hemithorax in as safe a position as possible (Figure 55.6).

The risk of recurrent pneumothorax is increased after the first episode. The best estimates of recurrence rates are:

- of patients who experience a first event, only about one-third experience recurrence;
- of those who have a second episode, about one-half go on to experience a third episode;
- those who have had three episodes will probably go on to have repeated recurrences.

Current recommendations from the British Thoracic Society are that in cases of persistent air leak following drain insertion or failure of the lung to re-expand, an early (3–5 days) thoracic surgical opinion should be sought. Other indications for thoracic surgical referral are given (Summary box 55.1).

Summary box 55.1

Indications for surgical intervention for pneumothorax

- Second ipsilateral pneumothorax
- First contralateral pneumothorax
- Bilateral spontaneous pneumothorax
- Spontaneous haemothorax
- Professions at risk (e.g. pilots, divers)
- Pregnancy

Current recommendations focus on the use of small bore (10–14 Fr) chest drains, usually of a Seldinger-type inserted ideally under ultrasound guidance. However, knowledge of the role of the 'surgical' chest drain and how to safely insert it is still required.

Inserting and managing a chest drain

An intercostal tube connected to an underwater seal is central to the management of chest disease; however, the management of the pleura and of chest drains can be troublesome, even in experienced hands.

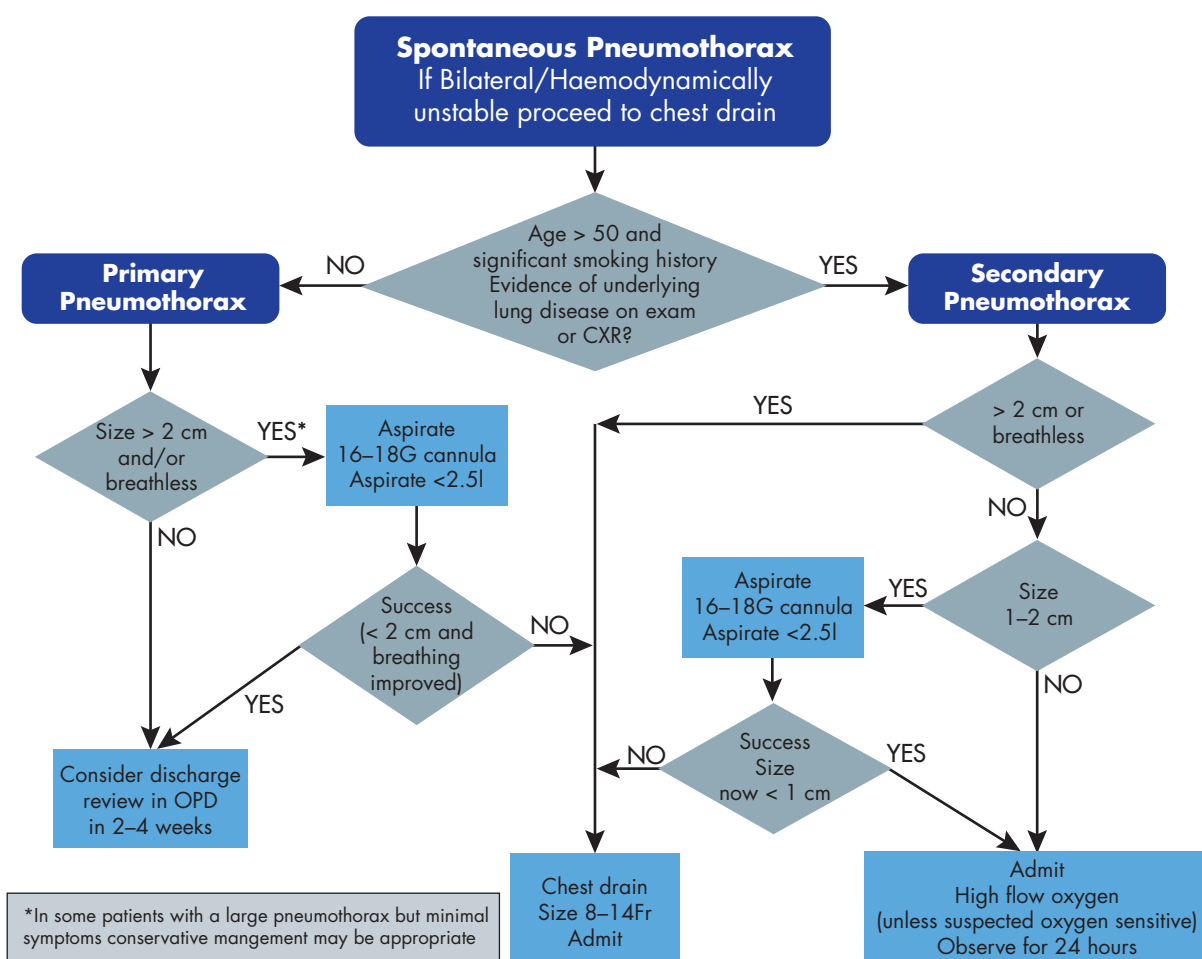

Figure 55.6 British Thoracic Society (BTS) guidelines on management of spontaneous pneumothorax (2010) (adapted from www.bts.org.uk).

Figure 55.7 Insertion of chest drain: (a) triangle of safety; (b) penetration of the skin, muscle and pleura; (c) blunt dissection of the parietal pleura; (d) suture placement; (e) gauging the distance of insertion; (f) digital examination along the tract into the pleural space; (g) withdrawal of central trocar and positioning of drain; (h) underwater seal chest drain bottle.

The safest site for insertion of a drain (Figure 55.7) is in the triangle that lies:

- anterior to the mid-axillary line;
- above the level of the nipple;
- below and lateral to the pectoralis major muscle.

This will ideally find the fifth space. The technique includes the following:

- Meticulous attention to sterility throughout.
- Adequate local anaesthesia to include the pleura.
- Sharp dissection only to cut the skin.
- Blunt dissection with artery forceps down through the muscle layers; these should only be the serratus anterior and the intercostals.
- An oblique tract, so that the skin incision and the hole in

the parietal pleura do not overlie each other and the drain is in a short tunnel, which reduces the chance of entraining air.

- A drain for pneumothorax and haemothorax should aim towards the apex of the lung. A drain for pleural effusion or empyema should be nearer the base. The drain should pass over the upper edge of the rib to avoid the neurovascular bundle that lies beneath the rib.
- The retaining stitch should be secure, but not obliterate the drain.
- A vertical mattress suture is inserted for later wound closure. This is vital for pneumothorax management, but should be omitted if the drain is for empyema (provided there is adherence of the pleura) because that tract should lie open.
- Connect the drain to an underwater seal device which functions as a one-way valve.
- After completion, check that the drain has achieved its objective by taking a chest x-ray.

It is preferable not to apply suction to the drain or to clamp it. The danger is that the clamp may be applied for transport and forgotten. Dangers of disconnection and siphoning are small or best averted in other ways apart from clamping. A bubbling drain should (almost) never be clamped. Remove the drain when it no longer has a function (Summary box 55.2).

Summary box 55.2

Suction on a pleural tube

- Beware! Inserting the drain, and not the suction, is the life-saving manoeuvre
- If the lung is reluctant to expand, the suction deviates the mediastinum
- If the lung is fragile, it may worsen an air leak

Definitive management of pneumothorax

Pleurectomy and pleurodesis

Surgery for pneumothorax can be performed by video-assisted thoracoscopic surgery (VATS) or as an open procedure (thoracotomy).

The object of the exercise is three-fold:

- to deal with any leaks from the lung;
- to search for and obliterate any blebs and bullae (**Bullectomy**);
- to make the visceral pleura adherent to the parietal pleura so that any subsequent leaks are contained and the lung cannot completely collapse.

Pleural adhesion is achieved in one of three ways:

- **Pleurectomy:** systematically strip the parietal pleura from the chest wall.
- **Pleural abrasion:** a scourer is used to scrape off the slick surface of the parietal pleura.
- **Chemical pleurodesis:** usually talc is used and is insufflated into the chest cavity.

Pleural effusion

Pleural effusion can be readily understood with reference to the physiological mechanisms governing the flux of pleural fluid given above. Pleural effusions are divided into exudates and

transudates, depending on protein content (more (exudates) or less (transudates) than 30 g/L), and characterised further according to glucose content, pH and lactate dehydrogenase content. The following are the most common ways in which the pleural fluid balance is disturbed:

- **Elevated pulmonary capillary pressure.** If left atrial pressure rises, the pulmonary capillary pressure must rise with it, whether as a result of impaired cardiac performance or an overloaded circulation.
- **Reduced intravascular oncotic pressure.** If the plasma proteins fall because of renal or hepatic disease or malnutrition, the absorption mechanism fails.
- **Accumulation of pleural protein** due to obstruction of the mediastinal lymphatics secondary to lymphoma or cancers that invade the lymphatic system.
- **Excessive permeability of the capillaries to fluid and protein** as in inflammatory diseases, particularly the collagen vascular diseases. Of particular importance to the surgeon is the effusion associated with pleural infection (empyema) and malignant effusions.

Malignant pleural effusion

Pleural effusion is a common complication of cancer. This may be due to:

- lung cancer;
- pleural involvement with primary or secondary malignancy;
- mediastinal lymphatic involvement.
- **Lung cancer.** There may be direct involvement of the parietal and/or visceral pleura, collapse of the lung parenchyma and spread to the mediastinal lymphatics, or a combination of these, causing pleural fluid accumulation. It is usually regarded as a feature that puts lung cancer beyond surgical cure.
- **Pleural malignancy.** The only primary malignancy of the pleura seen with any regularity is malignant mesothelioma. This is a consequence of asbestos exposure with few exceptions. The peak of asbestos imports into the UK was from 1960 to 1975 and the incidence of mesothelioma is rising and is expected to peak in around 2015. Mesothelioma commonly presents with breathlessness because of pleural effusions, pain and systemic features of malignancy. Diffuse seeding of the parietal and visceral pleura is a common pattern of dissemination of cancers, particularly adenocarcinoma of any origin.
- **Mediastinal lymphatic involvement.** In many instances, particularly in breast cancer, there is no evident disease in the pleura. The disease is in the mediastinal lymphatics, which are obstructed, and this upsets the balance of physiological forces that control pleural fluid.

Surgery for patients with malignant pleural effusion

The surgeon has two roles:

- to make the diagnosis;
- to achieve effective palliation by draining the fluid and pleurodesis.

Diagnosis

Pleural biopsy can be obtained by a range of techniques with VATS being the most common. An unequivocally positive

biopsy is useful but a negative biopsy may be a sampling error (Summary box 55.3).

Summary box 55.3

Biopsy of the pleura

- Cytological examination of the pleural fluid (low yield)
- Abrams' needle (low yield in malignancy)
- Computed tomography (CT)-guided needle biopsy of a suspicious area
- Video-assisted thoracoscopic surgery biopsy
- Open surgical biopsy

Pleural infection and empyema

Empyema is the end stage of pleural infection from any cause. It most commonly results from infection of the underlying lung by pneumonia or lung abscess, but can occur as a complication of any thoracic operation. It is seen if a traumatic haemothorax becomes infected or in the course of management of pneumothorax or pleural effusions. It may be associated with pus under the diaphragm (Table 55.3). The pathological diagnosis requires the presence of thick pus with a thick cortex of fibrin and coagulum over the lung.

Table 55.3 Conditions that predispose to empyema formation.

Pulmonary infection	Unresolved pneumonia Bronchiectasis Tuberculosis Fungal infections Lung abscess
Aspiration of pleural effusion	Any aetiology
Trauma	Penetrating injury Surgery Oesophageal perforation
Extrapulmonary sources	Subphrenic abscess
Bone infections	Osteomyelitis of ribs or vertebrae

When empyema presents *de novo* it usually follows pneumonia and three phases are described:

- 1 In the exudative phase, there is protein-rich (>30 g/L) effusion. If this becomes infected with the organisms from the lung (typically *Streptococcus milleri* and *Haemophilus influenzae* in children), the scene is set for empyema. At this stage, antibiotics may be all that is required. Aspiration or drainage to dryness in addition is preferred.
- 2 Over the next days, the fluid thickens to what is known as the fibrinopurulent phase. Drainage at this stage is prudent as antibiotics alone are unlikely to be curative.
- 3 The organising phase causes the lung to be trapped by a thick peel or 'cortex' for which surgical management may be required.

Surgical management of pleural effusions and infections

Thoracoscopy or video-assisted thoracoscopic surgery

The direct-vision thoracoscope has been used for many years, but its use was limited mainly to performing biopsies. The instrument had a limited view and was uncomfortable to use for any length of time. All this has changed since the advent of video-assisted thoracoscopy (Figure 55.8) where the surgeon's hands are freed because the camera is attached to the thoracoscope, which can be operated by an assistant with the image displayed on a television screen. The surgeon is able to manipulate instruments with both hands to perform a variety of procedures. The number of ports required depends on the type and complexity of the surgery. The patient is usually positioned with the diseased side uppermost, having had a double lumen endotracheobronchial tube placed by the anaesthetist to allow for single-lung ventilation.

Pneumonectomy, lobectomy and empyema drainage are all possible. However, lung biopsy and the treatment of recurrent pneumothorax are the most frequent indications. The principal advantage is that a large incision is avoided resulting in less postoperative pain and a more rapid recovery.

VATS drainage, pleural biopsy and talc pleurodesis

VATS drainage, pleural biopsy and talc pleurodesis is an increasingly performed procedure for managing patients with an undiagnosed or malignant pleural effusion. It can be performed using a single or two ports and allows for direct visualisation of the pleural cavity for complete drainage, multiple pleural biopsies and excellent talc insufflation to achieve pleurodesis.

VATS debridement of empyema

Pleural infection, particularly early in its evolution, requires drainage but once the fluid component becomes fibrinopurulent and loculated it requires surgical debridement which can often be achieved through a VATS approach. The lung is isolated

through the use of a double lumen tube, the patient is positioned disease side up, and the pleural cavity is entered. The fluid and debris are vigorously debrided, freeing the lung and allowing for re-expansion. At the end of the case, carefully positioned chest drains are placed to allow for dependent drainage. The drain/s must exit the skin anterior to the mid-axillary line otherwise the patient will have to lie on the drain(s), causing pain and possibly obstructing the tube. The drain should lie obliquely in its course through the skin and chest wall and into the pleura, or it will kink.

Following the procedure, the patient requires good analgesic control, typically patient controlled analgesia (PCA) and physiotherapy to help fully re-expand the lung prior to final removal of chest drains.

Decortication

If the lung fails to re-expand after drainage of the empyema, the more radical operation of decortication may be required (Figure 55.9). The fibrous cortex or peel from the entrapped underlying lung is removed so that the lung can expand to obliterate the pleural space. This is performed through a posterolateral thoracotomy and requires careful dissection to remove the parietal and visceral cortex, taking care not to damage the visceral pleura.

PRESENTATION OF LUNG DISEASE

Haemoptysis

Diseases causing repeated haemoptysis include carcinoma, bronchiectasis, carcinoid tumours and some infections. Severe mitral stenosis is now a rare cause. Patients with repeated haemoptysis should be investigated, at the very least by chest radiography and bronchoscopy. Haemoptysis following trauma may be from a lung contusion or injury to a major airway. Treatment depends on the underlying cause.

Common associated chest symptoms include cough with

Figure 55.8 Video-assisted thoracoscopic surgery (VATS) utilises modern thoracoscopic instruments and digital technology and avoids large incisions.

Figure 55.9 Chest computed tomography scan showing an empyema with a grossly thickened pleura.

or without sputum, pain, breathlessness, hoarseness and more general symptoms of systemic upset, including fatigue and loss of weight. Occasionally, chest disease may cause palpitation due to atrial fibrillation. Any of these symptoms in association with haemoptysis requires urgent investigation.

Investigation

Bronchoscopy

Flexible bronchoscopy may be performed with the patient awake and the oropharynx anaesthetised with topical lignocaine (Figure 55.10). The bronchoscope is passed into the nose or mouth and through the vocal folds under direct vision. As the scope is flexible, its tip can be directed into the segmental bronchi with ease. Tissue and sputum samples may be obtained for diagnostic purposes. There is a greater range of movement with this instrument, but the biopsies are relatively small and suction limited.

Rigid bronchoscopy requires general anaesthesia in most instances. It is ideal for therapeutic manoeuvres, such as removal of foreign bodies, aspiration of blood and thick secretions, and intraluminal surgery (laser resection or stent placement). The surgeon and the anaesthetist share control of the airway. Continuous electrocardiography (ECG) and pulse oximetry monitoring are now essential. The technique involves the operator standing behind the patient and lifting the maxilla by the upper teeth, using the middle finger and forefinger of the left

hand. The bronchoscope rests on the left thumb as it is introduced over the tongue in the midline. Care must be taken not to trap the lips or tongue between the teeth and the bronchoscope, and the fulcrum should be the left thumb and not the teeth. The bronchoscope is passed under direct vision into the oropharynx, behind the epiglottis, until the vocal folds are seen. Turning the instrument through 90° will help to negotiate the vocal folds; only then should the neck be extended.

The tracheal rings and the carina should be easily seen. Advancing the bronchoscope into the right and left main bronchus reveals the orifices of the more peripheral bronchi. Operability of an endobronchial tumour may be assessed in terms of its location (e.g. the proximity of a lesion to the carina). Complications are rare, but include bleeding, pneumothorax, laryngospasm and arrhythmia (Summary box 55.4).

Summary box 55.4

Biopsy hazards

- Bleeding disorders
- Systemic anticoagulation
- Pulmonary hypertension

Other techniques of biopsy of intrathoracic lesions are often necessary to confirm diagnosis, stage disease and plan treatment. The options range from percutaneous needle biopsy under radiological control, endobronchial ultrasound, to open-lung biopsy. However, high-quality, contrast-enhanced, multi-slice helical CT scanning will reduce the requirement for invasive assessment (Table 55.4).

Table 55.4 Uses of bronchoscopy.

Diagnostic	Confirmation of disease: carcinoma of the bronchus; inflammatory process; infective process
Investigative	Tissue biopsy
Preoperative assessment	Before lung resection Before oesophageal resection Persistent haemoptysis
Therapeutic	Removal of secretions Removal of foreign bodies Stent placement, endobronchial resection, etc.

Airway obstruction

Tracheal obstruction may present acutely as a life-threatening emergency or insidiously with little in the way of symptoms until critical narrowing and stridor occur. The more common causes of airway narrowing are outlined in Table 55.5.

Table 55.5 Causes of airway narrowing.

Intraluminal	Inhaled foreign body Neoplasm
Intramural	Congenital stenosis Fibrous stricture (post-intubation or tuberculosis)
Extramural	Neoplasm (thyroid cancer, secondary deposits) Aortic arch aneurysm

Figure 55.10 (a) Rigid and flexible bronchoscopes. (b) View past the carina into the left main bronchus with a tumour seen in the bronchial lumen.

Treatment depends on the underlying cause. Tracheostomy may be required to overcome the obstruction, but there are few indications to do this as an emergency. Tracheal replacement with artificial substitutes has so far been unsuccessful, but resection of up to 6 cm of trachea is now possible. Sleeve resections of the major bronchi are also possible.

Inhaled foreign bodies

This is a fairly common occurrence in small children and is often marked by a choking incident that then apparently passes. Surprisingly large objects can be inhaled and become lodged in the wider calibre and more vertically placed right main bronchus. There are three possible presentations:

- 1 asymptomatic;
- 2 wheezing (from airway narrowing) with a persistent cough and signs of obstructive emphysema;
- 3 pyrexia with a productive cough from pulmonary suppuration.

A chest x-ray is vital; even if the object is not radio-opaque, there may be other changes. An experienced anaesthetist is required. The procedure may be very difficult if there is a severe inflammatory reaction.

MALIGNANT LUNG TUMOURS

Primary lung cancer

Lung cancer is one of the most common cancers throughout the world. In the UK, there are 40 000 cases a year, making it the most common cause of cancer death. From the time of diagnosis, 80 per cent of patients are dead within one year and only 5 per cent survive for five years.

Surgical resection has a limited role in curative treatment because at the time of presentation many cases are locally advanced or widely disseminated and are beyond surgical cure. The proportion of lung cancers in which resection is attempted varies from fewer than 10 per cent in the UK to about 25 per cent in the United States. However, the thoracic surgeon working in a cancer team has a role in diagnosis, staging and palliation apart from resection in appropriate cases. The disease is so common that surgeons of all disciplines will encounter cases of lung cancer presenting with various manifestations.

Cigarette smoking is undoubtedly the major risk factor for developing bronchial carcinoma and accounts for 85–95 per cent of all cases. To a lesser extent, atmospheric pollution and certain occupations (radioactive ore and chromium mining) contribute. The risk is related to the lifetime burden of cigarette smoking, which is commonly quoted as ‘pack-years’ (a ‘pack’ being 20 cigarettes): the number of packs smoked per day multiplied by the number of years of exposure. In the UK, the mortality rate from lung cancer for individuals smoking more than 40 cigarettes per day is over 210 deaths per 100 000 population per year. This compares with a mortality rate of less than four deaths per 100 000 population per year in non-smokers.

Pathological types

For practical purposes, lung cancers are divided into small cell and non-small cell lung cancer (NSCLC), which are seen in a ratio of about 1:4:

- The pattern of disease, the prognosis and the results of treatment for small cell (also known as oat cell) carcinoma

differ from all other types sufficiently for these to be managed differently from the outset on the basis of the histological classification.

- Subdivisions of NSCLC according to histological characteristics are much less important, but pathological staging is critical to treatment and outcome.

Histological classification of lung cancer

- **Small cell lung cancers** were known as oat cell cancers because of the packed nature of small dense cells. These represent about 20 per cent of all lung cancer. They tend to metastasise early to lymph nodes and by blood-borne spread. The median survival is measured in months. The tumours are very responsive to chemotherapy such that median survival may be doubled (but is still short), but they are rarely, if ever, cured. Surgery is rarely offered unless in very limited stage disease.
- **Adenocarcinoma** is now the most common of the NSCLC types, having overtaken squamous cancer. The increasing incidence is partly due to an increasing incidence in women and may be the result, in part, of a move towards lower-tar cigarettes that are inhaled more deeply to get the same effect.
- **Squamous carcinoma** typically appears as a cavitating tumour.
- **Large cell undifferentiated** is a discrete histological type of NSCLC and is included within neuroendocrine tumours.
- **Bronchioalveolar carcinoma** has a distinct pattern of growth following the pre-existing pulmonary architecture and is thus much less dense; it appears as a patchy diffuse shadow (‘ground glass’) on the radiograph, rather than a solid mass and has a histological appearance to match. After resection, it can appear in another lobe or the other side.

Accurate diagnosis and staging of the tumour are vital if surgery is to be considered.

Clinical features

Clinical features of lung carcinoma depend on:

- the site of the lesion;
- the invasion of neighbouring structures;
- the extent of metastases.

Common symptoms include a persistent cough, weight loss, dyspnoea and non-specific chest pain.

- Haemoptysis occurs in fewer than 50 per cent of patients presenting for the first time.
- Cough, or a changed cough, is a common presentation but non-specific in this population.
- Severe localised pain suggests chest wall invasion with the infiltration of an intercostal nerve. Invasion of the apical area may involve the brachial plexus, leading to Pancoast’s syndrome.
- Dyspnoea may come from loss of functioning lung tissue, lymphatic invasion or the development of a large pleural effusion.
- Pleural fluid is an ominous feature and the presence of blood in a pleural effusion suggests that the pleura has been directly invaded.
- Clubbing (Figure 55.11) and hypertrophic pulmonary osteoarthropathy accompany some lung cancers and may resolve with excision of the primary lesion.
- Invasion of the mediastinum may result in hoarseness (because of recurrent laryngeal nerve involvement), dysphagia

(because of the involvement of, or extrinsic pressure on, the oesophagus) and superior vena caval obstruction.

- Small cell carcinoma is associated with the development of myopathies including the Eaton–Lambert syndrome, which is similar to myasthenia gravis (Summary box 55.5).

Summary box 55.5

Symptoms of lung cancer

- Haemoptysis <50% of patients
- Cough, new or changed pattern
- Pain
- Dyspnoea
- Clubbing
- Hoarseness
- Myopathies

Treatment of lung cancer

Careful investigation is required to determine which tumours are operable and will benefit from a major thoracic resection. The internationally agreed tumour–node–metastasis (TNM) staging system gives prognostic information on the natural history of the disease. Tumours graded up to T3, N1, M0 can be encompassed within an anatomical surgical resection and have a much improved prognosis when treated surgically, so the tumour must be staged accurately before resection (Table 55.6). A number of non-tumour factors, including the general fitness of the patient and the results of lung function tests, help to determine the appropriate treatment. In patients with incurable disease, treatment is palliative to maximise quality of life and disease-free survival.

Survival

Carcinoma of the bronchus generally has a low survival rate after diagnosis (Table 55.7). Important factors in determining

Table 55.6 The international tumour–node–metastasis (TNM) staging system.

Primary tumour (T)	
T0	No evidence of primary tumour
T1	Tumour ≤3 cm ^a , surrounded by lung or visceral pleura, no bronchoscopic evidence of invasion, more proximal than the lobar bronchus
	T1a, Tumour ≤2 cm
	T1b, Tumour >2, but ≤3 cm
T2	Tumour >3, but ≤7 cm ^a or tumour with any of the following ^b : invades visceral pleura, involves main bronchus ≥2 cm distal to the carina, atelectasis/obstructive pneumonia extending to hilum, but not involving the entire lung
	T2a, Tumour >3, but ≤5 cm ^a
	T2b, Tumour >5, but ≤7 cm ^a
T3	Tumour >7 cm or directly invading chest wall, diaphragm, phrenic nerve, mediastinal pleura, or parietal pericardium; or tumour in the main bronchus <2 cm distal to the carina ^c ; or atelectasis/obstructive pneumonitis of entire lung; or separate tumour nodules in the same lobe
T4	Tumour of any size with invasion of the mediastinum or involving the heart, great vessels, trachea, recurrent laryngeal nerve, oesophagus, vertebral body or carina, or separate tumour nodules in a different ipsilateral lobe
Nodal involvement (N)	
N0	No demonstrable metastasis or regional lymph node
N1	Metastasis to lymph nodes in the peribronchial or the ipsilateral hilar region, or both, including direct extension
N2	Metastasis to the ipsilateral, mediastinal and subcarinal lymph nodes
N3	Metastasis to the contralateral mediastinal lymph nodes, contralateral hilar lymph nodes, ipsilateral or contralateral scalene or supraclavicular lymph nodes
Distant metastasis (M)	
M0	No known distant metastasis
M1a	Separate tumour nodules in a contralateral lobe, or tumour with pleural nodules or malignant pleural dissemination ^d
M1b	Distant metastasis
Special situations	
T ₁ N ₁ M	T, N or M status not able to be assessed
Tis	Focus of <i>in situ</i> cancer
T1	Superficial spreading tumour of any size, but confined to the wall of the trachea or mainstream bronchus

^aIn the greatest dimension.

^bT2 tumours with these features are classified as T2a if ≤5 cm.

^cThe uncommon superficial spreading tumour in central airways is classified as T1.

^dPleural effusions that are cytologically negative, non-bloody, transudative, and clinically judged not to be due to cancer are excluded.

prognosis are the histological type of the tumour, the spread (stage) and the general condition of the patient. Early detection and surgical resection offer the best hope for cure.

Diagnosis and staging

Increasing emphasis in recent years has been the early detection of lung cancer, with guidance on symptoms and signs of potential lung cancer that require urgent chest x-ray and referral to lung cancer team (Table 55.8).

Non-invasive investigations

Chest x-ray

A chest x-ray will detect most lung cancers but some, particularly early curable tumours, are hidden by other structures. Secondary effects such as pleural effusion, distal collapse and raised hemidiaphragm may be evident (Figure 55.12).

Computed tomography

This is the first investigation in suspected lung cancer. The surgeon needs to know if the primary is resectable (T stage) and which if any lymph nodes are involved (N stage). Lymph nodes of

Figure 55.11 Example of finger clubbing in a patient with bronchogenic carcinoma.

Table 55.7 Survival table following operation for carcinoma of the bronchus.

	(%)
Five-year survival according to presurgical staging	
Stage I	56–67
Stage II	39–55
Stage IIIa	23
Stage IIIb	<10
Five-year survival according to cell type	
Squamous cell carcinoma	35–50
Adenocarcinoma	25–45
Adenosquamous carcinoma	20–35
Undifferentiated carcinoma	15–25
Small cell carcinoma	0–5

Figure 55.12 Chest x-ray of carcinoma of the lung. This patient has a large mass in the right upper lobe, causing Horner's syndrome.

Table 55.8 Recent National Institute for Health and Clinical Excellence (NICE) guidance on referral in patients with suspected lung cancer.

Symptoms and signs indicating urgent chest x-ray	Offer urgent chest x-ray to patients presenting with haemoptysis, or any of the following if unexplained or present for more than 3 weeks:	Cough Chest/shoulder pain Dyspnoea Finger clubbing Signs suggesting metastases (for example, in brain, bone, liver or skin) Weight loss Chest signs Hoarseness Cervical/supraclavicular lymphadenopathy
Symptoms and signs indicating urgent referral	Offer urgent referral to lung cancer multidisciplinary team (MDT) (usually the chest physician) while waiting for chest x-ray results if any of the following are present: Offer urgent referral to lung cancer MDT (usually the chest physician) if:	Persistent haemoptysis in a smoker or ex-smoker older than 40 years Signs of superior vena cava obstruction (swelling of the face and/or neck with fixed elevation of jugular venous pressure) Stridor A chest x-ray or CT scan suggests lung cancer (including pleural effusion and slowly resolving consolidation) or Chest x-ray is normal, but there is a high suspicion of lung cancer

Figure 55.13 Paratracheal lymphadenopathy shown on a computed tomography scan.

more than 2 cm in diameter are likely to be involved in the disease (70 per cent) (Figure 55.13) and those less than 10 mm in the shorter axis are unlikely to be involved. If the presence of cancer in the nodes is critical to management, further evidence from positron emission tomography with radiolabelled fluorodeoxyglucose

(FDG-PET) or biopsy (see below) is essential. Remote metastases to the liver, adrenals or elsewhere may be detected.

Positron emission tomography

The patient is given radiolabelled FDG, which is taken up by all metabolising cells but more avidly by cancer cells. The FDG enters the Krebs's cycle but cannot complete it and accumulates in proportion to the glucose avidity of the cells. High accumulation is associated with lung cancers and secondaries. Infection or other inflammation, and lymphadenopathy secondary to it, are also FDG avid (Figure 55.14).

Sputum cytology

Sputum cytology may reveal malignant cells, but the false-negative rate is high.

Invasive investigations

Once lung cancer is suspected, diagnosis and further staging are sought. The choice of investigation depends on the position of the primary tumour in the lung (peripheral or central) and the clinical stage of the cancer (presence of enlarged lymph nodes or metastasis).

Bronchoscopy

A flexible bronchoscopy is usually performed under sedation particularly in more centrally placed lung cancers. It allows assessment of the segmental airway, cytological testing through brushing and washing of the concerned segmental bronchi and trans-bronchial needle aspiration (TBNA).

Endobronchial ultrasound

Endobronchial ultrasound (EBUS) allows bronchoscopic assessment of suspicious mediastinal lymph nodes with an ultrasound probe incorporated into the tip of the bronchoscope to aid TBNA (Figure 55.15). Endoscopic ultrasound (EUS) is a similar technique that by passing down the oesophagus allows fine needle aspiration (FNA) of less approachable mediastinal lymph nodes.

Computed tomography-guided biopsy

Percutaneous CT-guided FNA may give a good yield of cells for cytological examination. Alternatively, a core of tissue can be obtained for formal histology. These techniques are best for larger and more peripheral lesions. Pneumothorax is common (30 per cent), but rarely requires intercostal tube drainage. The contraindications include poor respiratory reserve when even a small pneumothorax would be hazardous.

Surgical diagnosis and staging

Mediastinoscopy, mediastinotomy, VATS or thoracotomy lymph node/lung biopsy are aimed at establishing a tissue

Figure 55.14 Multiple FDG-avid mediastinal lymph nodes shown on a positron emission tomography/computed tomography scan (courtesy of Dr Sally Barrington).

Figure 55.15 Endobronchial ultrasound (EBUS) allows accurate diagnosis of enlarged mediastinal lymph nodes for diagnosis and staging of lung cancer.

diagnosis and assessing the degree of spread (staging), which determines resectability. Histological proof of the status of mediastinal nodes may be important to avoid unnecessary thoracotomy for incurable cancers and, conversely, to not deny surgery to patients whose lymph nodes are enlarged but benign.

Mediastinoscopy

This procedure is performed under general anaesthesia with the patient supine and his or her neck extended (Figure 55.16). A transverse incision is made 2 cm above the sternal notch and deepened until the strap muscles are reached. These are retracted laterally and the thyroid isthmus is retracted superiorly to reveal the pretracheal fascia. Careful blunt dissection in this plane allows

Figure 55.16 Mediastinoscopy. The mediastinoscope slides down immediately in front of the trachea, behind the aortic arch, and behind and between the great vessels of the head and neck.

Sir Hans Adolf Krebs, 1900–1981, Professor of Biochemistry, The University of Oxford, Oxford, UK. Was elected as a Fellow of the Royal Society of London in 1947; he is known best for identification of the urea cycle and the citric acid cycle. The latter known as the Krebs cycle, earned him a share of the Nobel Prize in Physiology or Medicine in 1953.

access to the paratracheal and subcarinal nodes. A mediastinoscope is introduced for direct visualisation and biopsy. Great caution should be used in the presence of superior vena caval obstruction. Complications include pneumothorax and haemorrhage.

Mediastinotomy

An incision is made through the second intercostal space to gain access to some of the mediastinal lymph nodes on the affected side. On the left, this includes lymph nodes in the para-aortic or sub-aortic fossa. Damage to the internal mammary artery and the phrenic nerve must be avoided. Mediastinal extension of tumour can also be assessed, for example left upper lobe tumours which invade the mediastinum around the aortic arch.

These techniques may also be used in the diagnosis of other mediastinal conditions, including:

- lymphoma;
- anterior mediastinal tumours;
- thymoma;
- sarcoid, tuberculosis or any other cause of lymphadenopathy.

VATS mediastinal lymph node and lung biopsy

For inaccessible mediastinal lymph nodes, or when diagnosis of the lung tumour has not been possible through radiological or bronchoscopic techniques, VATS performed through two or three ports allows diagnosis of the tumour, staging of the mediastinum and gives the opportunity to assess the likely operability of the lung cancer.

Surgical approach to lung cancer resection

Thoracotomy

Although the most frequent reason for thoracotomy is lung cancer, all surgeons dealing with trauma should be able to perform a thoracotomy, if required. The standard route into the thoracic cavity is through a posterolateral thoracotomy. The incision is used for access to the:

- lung and major bronchi;
- pleura;
- thoracic aorta;
- oesophagus;
- posterior mediastinum.

A double-lumen endotracheal tube is used to allow ventilation of one lung while the other is collapsed, to facilitate surgery and to protect the non-operated lung and retain control of ventilation (Figure 55.17).

Figure 55.17 The double-lumen tube permits separate ventilation of the right and left lungs.

The patient is turned to the lateral position with the affected side up (Figure 55.18). The lower leg is flexed at the hip and the knee, with a pillow between the legs. Table supports are used to maintain the position and additional strapping is used at the hips for stability. The patient's hips are placed below the break point of the operating table to allow opening of the intercostal spaces as the table is angulated. The upper arm may be supported by a bracket in a position of 90° flexion. The lower arm is flexed and positioned by the head. It is important for both the surgeon and the anaesthetist to be completely satisfied with the position of the patient and the tube and lines at this stage.

- The incision passes 1–2 cm below the tip of the scapula, and extends posteriorly and superiorly between the medial border of the scapula and the spine.
- The incision is deepened through the subcutaneous tissues to the latissimus dorsi. This muscle is divided with coagulating diathermy, taking care over haemostasis.
- A plane of dissection is developed by hand deep to the scapula and serratus anterior. The ribs can be counted down from the highest palpable rib (which is usually the second) and the sixth rib periosteum is scored with the diathermy near its upper border. A periosteal elevator is used to lift the periosteum off the superior border of the rib or alternatively the intercostal muscle is cut with diathermy just above the rib (Figure 55.19).
- This reveals the pleura, which may be entered by blunt dissection. A rib spreader is inserted between the ribs and opened gently to prevent fracture.
- Exposure may be facilitated by dividing the rib at the costal angle or by dividing the costotransverse ligament. Resection of a rib is not usually required.
- The anaesthetist is now able to deflate the affected lung to allow a better view of the intrathoracic structures.

In an emergency thoracotomy for penetrating wounds of the heart, a more anterior approach is used and no specialised

supporting equipment is required (Figure 55.20). The incision is taken down to the fourth or fifth rib with a scalpel, and using scissors the pleural cavity opened. This gives rapid access to the left pleural cavity in cases of massive left haemothorax and the pericardium if cardiac tamponade is suspected. A left anterior thoracotomy can be quickly converted to a clamshell or bilateral thoracotomy if necessary.

Figure 55.19 Incision and layers encountered during anterolateral thoracotomy. A The latissimus dorsi is divided in line with the skin incision. B If the serratus anterior is divided, it should be close to its attachment to ribs 6, 7 and 8. It can be left intact and mobilised along its inferior border. C The intercostal muscles are stripped off the upper border of the rib.

Figure 55.18 Correct positioning for thoracotomy.

Figure 55.20 Emergency left anterior thoracotomy for access to the heart. Requires no special supports or devices.

Following the operation, 24–28 Fr chest drain/s are placed, typically through the seventh or eighth intercostal space, anterior to the mid-axillary line, so that the patient does not lie on them. Even if the site to be drained is posterior, as in empyema, the drains are tunnelled to come out more anteriorly for easier management. The thoracotomy is closed using paracostal sutures placed around the rib above and below to reapproximate the ribs or alternatively intercostal muscle is sutured to the intercostal muscle below the stripped rib with a continuous absorbable suture. The fascia and muscle layer are closed in layers using an absorbable suture. Skin closure is a matter of personal preference.

Analgesia is an important aspect of postoperative care and the process may be started prior to thoracotomy with an epidural catheter placed by the anaesthetist, or intraoperatively by infiltrating the intercostal nerves in the region of the incision with a long-acting local anaesthetic via a surgically sited paravertebral catheter. Various strategies have been developed to deliver analgesics postoperatively to facilitate a normal breathing pattern.

Video-assisted thoracoscopic surgery

Various approaches utilising thoracoscopic techniques can be used to gain access to the chest cavity and facilitate lung resection. A combination of a smaller thoracotomy incision and VATS has been described, but increasingly lung resections can be performed through three or four port incisions and the dissection of hilar structures completed entirely through VATS. The technique avoids rib-spreading and appears to reduce post-operative pain, length of stay and aids a speedier recovery.

Surgical management of lung cancer

The principle of surgery is to remove all cancer (the primary and the regional lymph nodes), but to conserve as much lung

as possible. The selection of patients in terms of the stage of the lung cancer and fitness to undergo such surgery is paramount. Surgery with curative intent is offered to patients with early stage lung cancer (T1–3, N0–1) (Table 55.9). Assessment of a patient's fitness to undergo lung cancer resection involves considering premorbid conditions which can be aided using risk scores such as Thorascore, cardiovascular function and lung function (Table 55.10). Lung function particularly will aid the surgeon in selecting the type of procedure offered and likely breathlessness or dyspnoea following lung resection.

Table 55.9 National Institute for Health and Clinical Excellence (NICE) recommendations for surgery for non-small cell lung cancer.

Surgery with curative intent for non-small cell lung cancer (NSCLC)
Offer patients with NSCLC who are fit for surgery, open or thoracoscopic lobectomy as the treatment of first choice. If complete resection is possible, consider segmentectomy or wedge resection for patients with smaller tumours (T1a–b, N0, M0) and borderline fitness
Offer more extensive surgery (bronchoangioplasty surgery, bilobectomy, pneumonectomy) only when needed to obtain clear margins
Perform hilar and mediastinal lymph node sampling or en bloc resection for all patients undergoing surgery with curative intent
For T3 NSCLC with chest wall involvement, aim for complete resection by extrapleural or en bloc chest wall resection

Table 55.10 National Institute for Health and Clinical Excellence (NICE) recommendations for assessing fitness for treatment with curative intent (including surgery).

Perioperative mortality	Consider global risk score, such as Thorascore	Ensure patient is aware of risk before consenting
Cardiovascular function	Assess risk factors and cardiac functional capacity	Avoid surgery within 30 days of myocardial infarction (MI)
		Optimise primary cardiac treatment and begin secondary cardiac prophylaxis as soon as possible
		Offer surgery if two or fewer risk factors and good cardiac functional capacity
		Seek cardiology review if active cardiac condition, three or more risk factors or poor cardiac functional capacity
		Consider revascularisation before surgery in stable angina
		Continue anti-ischaemic treatment in perioperative period.
		Discuss perioperative platelet treatment if patient has a coronary stent
Lung function	Perform spirometry, measure T_lCO if disproportionate breathlessness or other lung pathology, perform segment count and assess exercise tolerance, and consider shuttle walk testing (cut-off 400 m) and cardiopulmonary exercise testing (cut-off 1.5 mL/kg/minute) if moderate to high risk of postoperative dyspnoea	Offer surgery if normal FEV_1 and good exercise tolerance or FEV_1 or T_lCO below 30% and patient accepts the risks of dyspnoea
		Offer radiotherapy with curative intent if lung function poor but patient is otherwise suitable for radiotherapy with curative intent and volume of irradiated lung is small

Choice of lung resection

Segmentectomy and wedge resection

Segmentectomy and wedge resections are performed in patients with small tumours and with borderline fitness through thoracotomy or VATS. Each lobe of the lung has segments which allows anatomical dissection and ligation of the segmental pulmonary artery, vein and bronchus (segmentectomy) (Figure 55.2) or non-anatomical excision can be performed (wedge resection) combined with removal of regional lymph nodes.

Lobectomy

Lobectomy remains the treatment of choice in patients with early stage lung cancer. The surgery can be performed via thoracotomy or VATS. Following dissection of the fissure and hilar structures, the branches of the pulmonary artery and veins to the lobe are isolated and ligated. The bronchus is usually stapled but can be sewn.

At the completion of the operation, the remaining lung is reinflated. Some air leak is common and usually settles within a few days. One or two intercostal drains are inserted. The patient does not routinely need intensive care and postoperative ventilation is best avoided. The 30-day mortality rate is 2–3 per cent, with morbidity such as chest infection or cardiac arrhythmia of around 10 per cent. The average length of stay is around 5–7 days.

Pneumonectomy

Pneumonectomy is removal of a whole lung and has a higher mortality rate (5–8 per cent). The surgeon must be satisfied that the patient is fit to tolerate this procedure from the preoperative work up. This procedure is reserved for either centrally placed tumours involving the main bronchus or those that straddle the fissure. At thoracotomy, an inspection of the lung and direct palpation of the mass will determine resectability and lymph node spread. Fixation of the tumour to the aorta, heart or oesophagus implies irresectability. Involvement of the mediastinal lymph node chain is associated with a poor prognosis. With modern preoperative imaging, resection is abandoned in only about 3 per cent of cases.

Pneumonectomy is anatomically more straightforward than lobectomy and involves dissecting and ligating the main pulmonary artery, the superior and inferior pulmonary veins and the main bronchus which is divided so that no blind stump remains (Figure 55.21). The technique of stump closure is important if a bronchopleural fistula is to be avoided. The tissues are carefully handled and the stump is usually stapled and sometimes covered using pleural, pericardium or a vascular pedicle such as an intercostal muscle. Drainage of the space is a matter of debate. Most use an underwater-seal drain and either leave it unclamped or unclamp it for 1 minute every hour until the drainage ceases; others prefer not to drain. The critical point is that no suction should be applied as there is now a sealed space with the mobile mediastinum on one side of it. The air in the pneumonectomy space is gradually absorbed and the fluid level within the space rises (Figure 55.22).

Complications of lung resection

- **Bleeding.** Bleeding should be avoidable by the use of a careful surgical technique, but may be severe in the presence of dense adhesions.
- **Respiratory infection.** Many of these patients are ex-smokers and so basal collapse and hypoxaemia are common post-operatively.
- **Persistent air leak.** Chest drains are placed at the time of surgery to deal with the air leak. Rarely, the air leak persists and the remaining lung does not expand. Repeat thoracotomy may then be necessary to seal the leak.
- **Bronchopleural fistula.** Bronchopleural fistula is a serious complication. Following pneumonectomy, the space left behind is initially filled with air. This is slowly reabsorbed and the space fills with tissue fluid. The fluid level rises until the air is finally reabsorbed. Dehiscence of the bronchial stump leads to the development of a bronchopleural fistula and the fluid in the space (which is almost inevitably infected) is expectorated in large quantities. This complication has a high morbidity and mortality rate.

Figure 55.21 Mediastinal structures after removal of right lung.

Figure 55.22 Chest radiographs (a) pre- and (b) post-pneumonectomy, with rising fluid level (c) in the left haemothorax.

The patient is nursed sitting up and turned so that the affected space is dependent, to prevent infected fluid from entering the remaining lung while arrangements are made to site a pleural drain. This should be connected to an underwater seal, but not suction. Bronchopleural fistulas are unlikely to resolve spontaneously and management is highly specialised.

Postoperative care

Patients have limited respiratory reserve following lung resection, so infection and fluid overload are to be avoided. Once air leaks have settled, the drains are removed. Mobilisation, breathing exercises and regular physiotherapy are begun as soon as the patient's condition permits.

Postoperative pain

It is important to deal with post-thoracotomy pain effectively so that a normal breathing pattern and gas exchange are achieved in the early postoperative period. Three strategies are routinely used in combination:

- patient-controlled analgesia (PCA) with intravenous boluses of opiates;
- paravertebral/extrapleural or epidural catheter-delivered local anaesthetic;
- background oral analgesia with paracetamol.

Long-term post-thoracotomy pain can be reduced by careful attention to detail during the operation. Sources of avoidable chronic pain include rib fracture and the entrapment of intercostal nerves during wound closure.

BENIGN LUNG TUMOURS

Benign tumours of the lung are uncommon and account for fewer than 15 per cent of solitary lesions seen on chest x-rays. A peripheral tumour usually causes no symptoms until it is large; a central tumour may present with haemoptysis and signs of bronchial obstruction while small. A tumour is likely to be benign if it has not increased in size on chest x-rays for more than two years or it has some degree of calcification; however, a tissue diagnosis is usually pursued.

Most benign nodules are granulomas (tuberculosis or histoplasmosis). The most common benign tumour is a hamartoma, a developmental abnormality containing mesothelial and endothelial elements. Diagnosis (and definitive treatment) is achieved by excision of the lesion. Any of the mesodermal elements of the lung may form a mesodermal tumour (chondroma, lipoma, leiomyoma). Deposits of amyloid may give similar radiographic appearances of a nodule (pseudotumour).

Bronchopulmonary carcinoid tumours

These carcinoid tumours are derived from the neuroendocrine cells of bronchial glands. Most (80 per cent) are found in the major bronchi and are characteristically slow growing and highly vascular. They are currently classified within a spectrum of neuroendocrine tumours. Most behave in a benign way; however, approximately 15 per cent metastasise. The patient often presents with a history of recurrent pneumonia or haemoptysis, but carcinoid syndrome is rare unless there is extensive pulmonary or hepatic metastases. Surgical excision is preferred as prognosis following complete resection is excellent (>90 per cent ten-year survival). Segmental or wedge resection may be sufficient for

a small peripheral tumour, while lobectomy or pneumonectomy may be necessary for central tumours. Where possible, a lung-sparing bronchoplastic or sleeve resection should be considered. This allows resection of proximal endobronchial lesions in an effort to preserve more distal, uninvolved lung parenchyma.

THE MEDIASTINUM

The mediastinum refers to the central area in the chest between the thoracic inlet and the diaphragm, between the right and left pleural surfaces and which extends from the inner aspect of the sternum to the vertebral column. It contains the heart, great vessels, trachea and the oesophagus, and is arbitrarily subdivided into compartments (superior, inferior, anterior, middle and posterior). Much of the regional lymph node chains draining the chest and its organs are also found in the mediastinum. Various surgical procedures to approach structures and particularly lymph nodes in the mediastinum have been described earlier under Surgical diagnosis and staging, and are performed usually as diagnostic procedures. The surgical approach when mediastinal tumours require resection depends on the anatomical location of the tumour (Figure 55.23) and includes median sternotomy for anterior mediastinal pathology, thoracotomy or VATS for posterior mediastinal pathology and transcervical (neck incisions) for superior mediastinal pathology. The middle mediastinum can usually be approached through thoracotomy or VATS.

Primary tumours of the mediastinum

Thymoma, neurogenic tumours, germ cell tumours and lymphoma are the usual primary tumours of the mediastinum.

- **Thymoma.** This is the most common mediastinal tumour, accounting for 25 per cent of the total and is derived from the thymus gland (Figure 55.24). Thymomas vary in behaviour from benign to aggressively invasive as reflected in the Masaoka classification system used to stage thymomas (Table 55.11). They are often related to myasthenia gravis (MG), a neuromuscular condition which can have a high associated incidence of thymomas, and interestingly may respond to

excision of the thymus gland even when the gland has no associated thymoma present. The only reliable indicator of malignancy is capsular invasion. Diagnosis and treatment are best achieved by complete thymectomy, which is usually performed as a median sternotomy. However, if the thymoma is small or when the patient has MG and the thymus is being excised as a treatment, a transcervical approach with or without an additional VATS procedure can be performed.

Table 55.11 Masaoka thymoma staging system.

Stage	Description
I	Macroscopically completely encapsulated Microscopically no capsular invasion
II	Macroscopic invasion into surrounding fatty tissue or mediastinal pleura Microscopic invasion into the capsule
III	Macroscopic invasion into neighbouring organs (pericardium, great vessels, lungs)
IVA	Pleural or pericardial dissemination
IVB	Lymphogenous or hematogenous metastasis

After Masaoka A *et al.*, *Cancer* 1981; **48**: 2485.

- **Germ cell tumour.** The anterior mediastinum is the most common site of extragonadal germ cell tumours. They account for 13 per cent of all mediastinal masses and cysts and contain elements from all three cell types (mesoderm, endoderm and ectoderm). They tend to present in young adults and 75 per cent are benign and cystic, although they may cause compression of neighbouring structures; hence, dermoid cysts are best excised. Malignancy is suspected if elevated levels of serum alpha-fetoprotein, human chorionic gonadotrophin and carcinoembryonic antigen are detected. After initial treatment with chemotherapy, a patient with tumour marker normalisation and a persistent mass on CT may be considered

Figure 55.23 Mediastinal pathology. Subdivisions of the mediastinum with the most common mediastinal masses.

Figure 55.24 Computed tomography scan showing a thymoma presenting as a mediastinal mass.

Figure 55.25 Computed tomography scan showing a right-sided paravertebral neurogenic tumour.

for surgical resection. If tumour markers fail to normalise, further chemotherapy is usually offered.

- **Lymphoma.** Lymphoma is a common cause of a mediastinal mass lesion, particularly the anterior mediastinum, and can lead to superior vena cava obstruction or other symptoms of local compression. The main treatment is chemotherapy, and surgery is rarely required apart from obtaining tissue for diagnosis.
- **Mesenchymal tumours.** Lipomas are common in the anterior mediastinum. Other mesenchymal tumours are very rare.
- **Thyroid.** Ectopic thyroid tissue (and parathyroid) may be found in the anterior mediastinum, but usually the mass is an extension of a thyroid lesion (retrosternal goitre). Excision of retrosternal thyroids may be required if there is local airway compression and stridor and can be performed via a transcervical incision, but occasionally median sternotomy may be required.
- **Neurogenic tumours.** These may derive from the sympathetic nervous system or the peripheral nerves and are more prevalent in the posterior mediastinum. They may be painful but are more often discovered accidentally on routine chest radiography and can be quite large (Figure 55.25). They include neuroblastoma in childhood, and schwannomas

Figure 55.26 Video-assisted thoracoscopic surgery (VATS) image of a neurogenic tumour attached to the posterolateral chest wall prior to excision.

and neurofibromas in adults, which are usually benign. Pheochromocytoma arises from the sympathetic chain and produces the characteristic endocrine syndrome. Excision of neurogenic tumours is generally recommended particularly if the patient is developing symptoms. This can be performed through a thoracotomy, though for smaller tumours a VATS approach can be used (Figure 55.26).

- **Enlarged mediastinal lymph nodes** are commonly involved by metastatic tumour mimicking a primary mediastinal lesion. Symptoms are generally secondary to compression or invasion of a structure within the mediastinum. Surgery, such as mediastinoscopy, is reserved for diagnosis only.

Other conditions of the mediastinum

Many of the primary tumours, such as neurogenic tumours and germ cell tumours, can present as cysts or have a cystic quality. In addition, the mediastinum can contain other cysts often with an embryological aetiology. Thymic cysts, pericardial cysts, bronchogenic and foregut cysts can all present asymptotically or with local compression (Figure 55.27). Surgical excision is recommended if diagnosis is unclear or the patient has symptoms.

MEDICAL CONDITIONS FOR WHICH SURGERY MAY BE REQUIRED

Bronchiectasis

Bronchiectasis is chronic irreversible dilatation of the medium-sized bronchi, which may occur following a suppurative pneumonia or bronchial obstruction. It is the pathological end-stage of a range of conditions. If generalised, it is almost never considered for surgical resection. Cases caused by whooping cough and measles are decreasing in frequency in developed countries.

Treatment

Removal of the bronchiectatic part of the lung for symptoms of bleeding, recurrent infection or copious symptoms can be very effective when the disease is localised.

Figure 55.27 Computed tomography scan of the chest showing a bronchogenic cyst splaying the carina.

Lung abscess

The causes of lung abscess are shown in Table 55.12. The chest radiograph shows a cavity with a fluid level or, in mycetoma, a fungal ball. Most acute abscesses resolve with appropriate antibiotic therapy and postural drainage. Surgery is avoided. Small radiologically sited drains are sometimes used in the intensive care unit.

Tuberculosis

Surgery is rarely indicated for tuberculosis in developed countries but, when it is, it must be combined with adequate anti-tubercular chemotherapy or the benefit of surgery will be lost (Summary box 55.6).

Summary box 55.6

Tuberculosis: indications for surgery

- Suspicious lesion on chest radiograph in which neoplasia cannot be excluded
- Chronic tuberculous abscess, resistant to chemotherapy
- Aspergilloma within a tuberculous cavity
- Life-threatening haemoptysis

Diagnosis

Surgical procedures may be necessary to establish the diagnosis if suspected clinically, but sputum or pus cultures are persistently negative.

Complications, such as an aspergilloma in a chronic cavity causing life-threatening haemoptysis, may require lobectomy.

Table 55.12 Causes of lung abscess.

Specific pneumonia	Streptococcal Staphylococcal Pneumococcal <i>Klebsiella</i> spp. Anaerobic
Bronchial obstruction	Carcinoma Carcinoid Foreign body Postoperative atelectasis
Chronic respiratory sepsis	Sinusitis Tonsillitis Dental infection
Septicaemia	
Penetrating lung injury	

Pulmonary sequestration

This describes a section of non-functional lung separated from the normal bronchial connection with other abnormalities of development, which often include a direct systemic arterial supply from the aorta. Venous return is to the pulmonary veins in the majority of cases. The segment becomes cystic and infected, resulting in the common appearance of a solid lung mass that may be homogenous or heterogenous, occasionally with cystic changes on CT scan. Interlobar sequestration occurs within the lung substance. It may present with recurrent chest infections and/or haemoptysis. Patients with extralobar sequestration are usually asymptomatic as air spaces are not present, and therefore usually present as an incidental finding.

Lung cysts

Developmental lung cysts have a tendency to become infected. Acquired lung cysts may contain air or fluid and may be single or multiple. Pulmonary hydatid disease is a cause in endemic areas. Air cysts (bullae) may be spontaneous, but may be secondary to emphysematous degeneration (Figure 55.28).

LUNG TRANSPLANTATION

Lung transplantation is an established therapy for those with end-stage parenchymal or pulmonary vascular disease, which is limited by the number of donor lungs available.

CHEST TRAUMA

The approach to trauma must be methodical and exact, because the signs, particularly in the presence of other injury, may easily be missed. The general principles of resuscitation and ATLS (advanced trauma and life support) must be followed.

Thoracic trauma is responsible for over 70 per cent of all deaths following road traffic accidents. Blunt trauma to the chest in isolation is fatal in 10 per cent of cases, rising to 30 per cent if other injuries are present. The indications for emergency room thoracotomy in blunt chest trauma include massive haemothorax,

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively in Prague, The Czech Republic; in Zurich, Switzerland; and at The Rush Medical College, Chicago, IL, USA.

Figure 55.28 (a) A large solitary bulla seen on videothoracoscopy. (b) The bulla deflated and rolled in preparation for staple resection.

suspected cardiac tamponade and witnessed cardiac arrest in the resuscitation area. Success rates are low. Penetrating thoracic wounds vary according to the prevalence of civil violence, with a mortality rate of 3 per cent for simple stabbing to 15 per cent for gunshot wounds. The indications for emergency room thoracotomy are similar to blunt chest trauma. The standard approach is a left anterior thoracotomy, unless the penetrating injury is in the right chest, however it may be necessary to extend the incision to bilateral thoracotomies or a clam-shell incision.

Early deaths after thoracic trauma are caused by hypoxaemia, hypovolaemia and tamponade. The first steps in treating such patients should be to diagnose and treat these problems as early as possible because they may be readily corrected. Young patients have a large physiological reserve, and serious injury may be overlooked until this reserve is used up, by which time the situation is critical and may be irretrievable. The best approach is to remain highly suspicious if life-threatening conditions are to be anticipated and treated. Early consultation with a regional thoracic centre is advised in cases of doubt. In an emergency, it is essential that experienced help is summoned.

Management of chest trauma is covered in detail in Chapter 28.

THE DIAPHRAGM

The diaphragm is the fibromuscular structure separating the thorax from the abdomen (Figure 55.29).

Figure 55.29 Diagram of sites of hernias. The usual sites of congenital diaphragmatic hernia: 1, foramen of Morgagni; 2, oesophageal hiatus; 3, foramen of Bochdalek (pleuroperitoneal hernia); and 4, dome.

Diaphragmatic disorders

Disorders of the diaphragm can be broadly classified as disorders of innervation, leading to paralysis of the diaphragm, with elevation and reduction of thoracic volume leading to breathlessness; or disorders of anatomy, which are further categorised into congenital diaphragmatic hernias or acquired hernias usually secondary to trauma. There are two well-recognised congenital sites where abdominal viscera can herniate into the chest (Figure 55.30):

- **The foramen of Morgagni.** A hernia in the anterior part of the diaphragm with a defect between the sternal and costal attachments. The most commonly involved viscus is the transverse colon.
- **The foramen of Bochdalek.** Through the dome of the diaphragm posteriorly.

Traumatic rupture of the diaphragm may occur with blunt trauma. Unless there is severe bleeding or strangulation of the viscera it is best managed at an interval. In a severely injured patient being ventilated, it can wait until other injuries are dealt with and weaning from the ventilator is being considered.

When the diaphragm is breached as in anatomical disorders, repair with either primary closure or with a mesh is usually possible via a thoracotomy. Diaphragmatic paralysis, particularly idiopathic unilateral paralysis can be plicated returning the diaphragm to a lower position and improving thoracic volume.

THE CHEST WALL

Tumours of the chest wall

These can be tumours of any component of the chest wall, i.e. bone, cartilage and soft tissue. They are treated similarly to those that occur in other sites and require specialist surgical input only if major resection and chest wall reconstruction are contemplated.

Other diseases of the chest wall

Congenital abnormalities are often incidental findings on chest x-ray (bifid rib), but there are some important exceptions.

Cervical rib and thoracic outlet syndrome

This rib is usually represented by a fibrous band originating from the seventh cervical vertebra and inserting onto the first thoracic rib. It may be asymptomatic, but because the subclavian artery and brachial plexus course over it, a variety of symptoms may occur. The lower trunk of the plexus (mainly T1) is compressed, leading to wasting of the interossei and altered sensation in the T1 distribution. Compression of the subclavian artery may result in a post-stenotic dilatation with thrombus and embolus formation. The diagnosis, assessment and surgery are fraught with uncertainties and are best left to those with a well-developed interest in this problem.

Figure 55.30 Chest x-ray of congenital diaphragmatic hernia. (a) Colon occupying a Morgagni hernia (courtesy of Dr Oliver Smith, Birmingham, UK). (b) Foramen of Bochdalek hernia on the left side in an infant. The left pleural cavity is occupied by intestine, the mediastinum is displaced to the right and the right lung is aerated very little.

Pectus excavatum

The sternum is depressed, with a dish-shaped deformity of the anterior portions of the ribs on one or both sides. It is never a cause of respiratory problems. It can be repaired to improve its cosmetic appearance either as an open procedure (the Ravitch procedure) which involves resecting the affected costal cartilages and mobilising the sternum, or as a minimally invasive technique, the Nuss procedure. A metal bar is placed behind the sternum to hold this central panel in its new position and has to be removed after a period of time (Figure 55.31a,b).

Pectus carinatum (pigeon chest)

In this condition, the sternum is elevated above the level of the ribs and treatment is offered for cosmetic reasons. The sternum is mobilised and allowed to fall back into place.

It often comes to light during the growth spurt at adolescence when, of course, the teenager is particularly sensitive about appearance. Most patients are asymptomatic and the only

Figure 55.31 (a) Insertion of preformed bar placed thoracoscopically beneath the pectus excavatum. (b) Chest x-ray following insertion of a metal bar bracing the sternum forward (the Nuss procedure).

cojustification for treatment is on cosmetic grounds. Some surgeons make a very good case for this, but the risk of morbidity and of a less than perfect result must be clearly spelt out to the patients and their parents. Surgery involves mobilising the sternum with the costal cartilages so that the sternum can be flattened to a more anatomical position. Surgery is best left until the late teens, when further growth of the chest wall is unlikely.

LEARNING OBJECTIVES

To understand:

- The nature and associated features of occlusive arterial disease
- The investigation and treatment options for occlusive arterial disease
- The principles of management of the severely ischaemic limb
- The nature and presentation of aneurysmal disease, particularly of the abdominal aorta
- The investigation and treatment options for aneurysmal disease
- The arteritides and vasospastic disorders

INTRODUCTION

Arterial disorders represent the most common cause of morbidity and death in Western societies. Much of this is due to the effects of atheroma on the arteries supplying the heart muscle (coronary thrombosis and myocardial infarction) and brain (stroke), although atheroma is also common at other sites. This chapter addresses diseases that are typically the province of the vascular surgeon, namely those affecting the arteries of the body, excluding those of the heart and those within the cranium.

ARTERIAL STENOSIS AND OCCLUSION

Cause and effect

Arterial stenosis or occlusion is commonly caused by atheroma, but can occur acutely as a result of emboli or trauma. Stenosis or occlusion produces symptoms and signs that are related to the organ supplied by the artery: e.g. lower limb (claudication, rest pain and gangrene); brain (transient ischaemic attacks and stroke); myocardium (angina and myocardial infarction); kidney (hypertension and renal failure) (Figure 56.1); intestine (abdominal pain and infarction). The severity of the symptoms is related to the size of the vessel occluded and whether the stenosis or occlusion occurs suddenly (acute) in a previously normal artery or gradually (chronic) with progressive narrowing of the artery over time. In chronic arterial narrowing, a collateral circulation may develop and provide an alternative route for blood flow which reduces symptoms until a critical stenosis or occlusion has developed (Figure 56.2).

Features of chronic arterial stenosis or occlusion in the leg

Intermittent claudication

Intermittent claudication is a cramp-like pain felt in the muscles that is:

Figure 56.1 Renal artery stenosis. Angiogram by retrograde femoral catheterisation. Note the post-stenotic dilatation.

- brought on by walking;
- not present on taking the first step (unlike osteoarthritis);
- relieved by standing still (unlike nerve compression from a lumbar intervertebral disc prolapse or osteoarthritis of the spine or spinal stenosis).

The distance that a patient is able to walk without stopping varies only slightly from day to day. It is altered by walking up hill, the speed of walking, carrying heavy weights and changes in general health, such as anaemia or heart failure.

The pain of claudication is usually felt in the calf because the superficial femoral artery is the most commonly affected (70 per cent of cases). Aortoiliac disease (30 per cent of cases) may cause

Figure 56.2 Right superficial femoral stenosis. Left superficial femoral occlusion with collateral vessels present, causing claudication.

thigh or buttock claudication. Buttock claudication in association with sexual impotence resulting from arterial insufficiency is eponymously called Leriche's syndrome. It is very rare.

Rest pain

Rest pain occurs with the limb at rest and is felt in the foot; it is exacerbated by lying down or elevation of the foot. Characteristically, the pain is worse at night and it may be lessened by hanging the foot out of bed or by sleeping in a chair. The pressure of bed clothes on the foot usually makes the pain worse.

Ulceration and gangrene

Ulceration occurs with severe arterial insufficiency and may present as a painful erosion between the toes or as shallow, non-healing ulcers on the dorsum of the feet, on the shins and especially around the malleoli. The blackened mummified tissues of frank gangrene are unmistakable (Figure 56.3), and superadded infection often makes the gangrene wet.

Figure 56.3 Severe chronic ischaemia with dry gangrene.

Rene Leriche, 1879–1955, Professor of Surgery, Strasbourg, France, described this syndrome (although the syndrome is credited to Leriche, the condition was first described by Robert Graham (1786–1845), physician at the Royal Infirmary in Glasgow, UK).

Colour, temperature, sensation and movement

An acutely ischaemic foot is often cold, white, paralysed and insensate. However, a chronically ischaemic limb tends to equilibrate with the temperature of its surroundings and may feel quite warm under the bedclothes. Chronic ischaemia does not produce paralysis and sensation is usually intact. Elevation of the limb produces pallor which changes to a red/purple colour when the limb is allowed to hang down (dependent rubor or the sunset foot sign). The capillary refill time may be elicited by pressing the skin of the heel or toe causing blanching and then releasing to allow colour to return (normally this takes 2–3 seconds, but may be prolonged to 10 seconds in severe ischaemia (Figure 56.4)).

Arterial pulses

It is standard practice to examine the femoral, popliteal, posterior tibial and dorsalis pedis arteries, together with the abdomen for an aneurysm which may coexist with occlusive disease. Diminution of a pulse can often be appreciated by comparing it with its opposite number. Popliteal pulses are difficult to feel and, if prominent, may suggest popliteal aneurysm. Pulsation distal to an arterial occlusion is usually absent although the presence of a highly developed collateral circulation may allow distal pulses to be normal – this is most likely to occur with an iliac stenosis. In this case, exercise (walking until claudication develops) usually causes the pulse to disappear as vasodilation occurs below the obstruction causing the pulse pressure to reduce. An arterial bruit, heard on auscultation over the pulse, indicates turbulent flow and suggests a stenosis. It is an unreliable clinical sign as tight stenoses often do not have bruits. A continuous 'machinery' murmur over an artery usually indicates an arteriovenous fistula (Summary box 56.1).

Summary box 56.1

Features of chronic lower limb arterial stenosis or occlusion

- Intermittent claudication
- Rest pain
- Dependent rubor or sunset foot
- Ulceration
- Gangrene
- Arterial pulsation diminished or absent
- Arterial bruit
- Slow capillary refilling

Relationship of clinical findings to site of disease

In most cases, the site of arterial obstruction can be determined from the symptoms and signs (Table 56.1). Severe ischaemia (rest pain, ulceration, gangrene) is usually caused by multilevel disease, e.g. iliac and femoropopliteal disease.

Risk factors and natural history

The common modifiable risk factors for occlusive arterial disease are smoking, hypertension, diabetes mellitus and hyperlipidaemia. The natural history of claudication is often to improve if the patient stops smoking and exercises. This encourages development of collaterals and the risk of limb loss is very low. For patients with rest pain or worse, intervention is usually required to prevent major amputation.

Figure 56.4 Colour changes with elevation (a) and dependency (b).

Table 56.1 Relationship of clinical findings to site of disease.

Aortoiliac obstruction	Claudication in both buttocks, thighs and calves Femoral and distal pulses absent in both limbs Bruit over aortoiliac region Impotence (Leriche)
Iliac obstruction	Unilateral claudication in the thigh and calf and sometimes the buttock Bruit over the iliac region
Femoropopliteal obstruction	Unilateral absence of femoral and distal pulses Unilateral claudication in the calf Femoral pulse palpable with absent unilateral distal pulses
Distal obstruction	Femoral and popliteal pulses palpable Ankle pulses absent Claudication in calf and foot

The best results from surgery are obtained by operation on the larger vessels, which allows a high volume of blood flow through bypass grafts. For instance, aortoiliac bypass is longer lasting than femorotibial bypass.

Investigation of arterial occlusive disease

Most patients with symptoms of arterial disease do not need invasive treatment, such as angioplasty or surgical reconstruction, and the decision whether or not to intervene can often be made without recourse to special investigations.

General investigation

Patients with arterial disease tend to be elderly and atherosclerosis is a generalised disease; if active intervention is contemplated, full assessment is essential. Many patients have age-related diseases, such as cardiac ischaemia, chronic obstructive

pulmonary disease and malignancy. Blood tests to exclude anaemia, diabetes, renal disease and lipid abnormalities should include a full blood count, blood glucose, lipid profile and serum urea and electrolytes. High blood viscosity (polycythaemia and thrombocythaemia) may be caused by smoking, but may also be associated with cancer; renal impairment (raised serum creatinine and low glomerular filtration rate (GFR)) may be caused by drugs and may be exacerbated by intravenous contrast agents used during angiography.

An electrocardiogram (ECG) may show coronary ischaemia, left ventricular hypertrophy or rhythm abnormalities, although a normal ECG does not rule out these conditions. More information may be gained by a cardiac echo or exercise testing. Arterial blood gases and pulmonary function test may be appropriate in patients with severe lung disease.

Doppler ultrasound blood flow detection

A hand-held Doppler ultrasound probe is very useful in the assessment of occlusive arterial disease (Figures 56.5 and 56.6). A continuous-wave ultrasound signal is transmitted from the probe at an artery and the reflected beam is picked up by a receiver within the probe itself. The change in frequency in the reflected beam compared with that of the transmitted beam is due to the Doppler shift, resulting from the reflection of the beam by moving blood cells. The frequency change may be converted into an audio signal that is typically pulsatile. Doppler ultrasound equipment can be used in conjunction with a sphygmomanometer to assess systolic pressure in small vessels. This is possible even when the arterial pulse cannot be palpated. Both the pressure and signal quality are important; a normal artery has a triphasic signal that can be detected by a trained observer. However, although the presence of a Doppler signal indicates moving blood, it does not necessarily indicate that the blood flow is sufficient to maintain limb viability and prevent limb loss.

Figure 56.5 Simple hand-held Doppler ultrasound probe.

Figure 56.6 Hand-held Doppler probe and sphygmomanometer used to determine systolic pressure in the dorsalis pedis artery, as part of assessing the ankle-brachial pressure index.

The ankle-brachial pressure index (ABPI) is the ratio of systolic pressure at the ankle to that in the arm. The highest pressure in the dorsalis pedis, posterior tibial or peroneal artery serves as the numerator, with the highest brachial systolic pressure being the denominator. Resting ABPI is normally about 1.0; values below 0.9 indicate some degree of arterial obstruction (claudication), less than 0.5 suggests rest pain and less than 0.3 indicates imminent necrosis. However, the values are merely a

guide and normal values may be present with intermittent claudication. Retesting after exercise can be useful; a normal ABPI may subsequently fall in patients with ischaemia. Artificially high readings can be caused by calcified, incompressible arteries which are often found in diabetics.

Duplex scanning

This major non-invasive technique uses B-mode ultrasound to provide an image of vessels (Figures 56.7 and 56.8). The image is created because of the varying ability of different tissues to reflect the ultrasound beam. A second ultrasound beam is then used to insonate the imaged vessel and the Doppler shift

Figure 56.7 Colour duplex scanner.

Figure 56.8 Colour duplex scan of carotid vessels in neck showing stenosis at common carotid bifurcation (courtesy of Dr Paul Allan, Royal Infirmary, Edinburgh, UK).

obtained is analysed by a computer. Most scanners now have colour coding which allows detailed visualisation of blood flow, turbulence, etc. Different colours indicate changes in direction and velocity of flow with areas of high flow usually indicating a stenosis. In experienced hands, Duplex scanning is as accurate as angiography and has the advantages of cost-effectiveness and safety. However, the aortoiliac segment can be difficult to visualise particularly in obese patients. A computed tomography (CT) angiogram can provide better imaging of this segment in these cases (see below).

Angiography

Angiography is invasive and only appropriate if intervention is being contemplated. It involves injection of a radio-opaque dye into the arterial tree by a percutaneous catheter method (Seldinger technique) usually involving the femoral artery (Figures 56.9 and 56.10). Hazards include bleeding, haematoma, false aneurysm formation, thrombosis, arterial dissection, distal embolisation, renal dysfunction and allergic reaction. Digital subtraction angiography (DSA) is now the standard technique whereby the images obtained are digitised by computer and the extraneous background (bone, soft tissues, etc.) is removed to provide clearer images. CT angiography and magnetic resonance (MR) angiography (Figure 56.11) are new techniques gaining in popularity although the image quality is not as good as DSA. They can be useful where duplex scanning is not possible (intrathoracic arteries) or produces poor images (aortoiliac segment). MR has the added advantage of avoiding the need for ionising radiation.

Figure 56.9 Seldinger needle and guidewire for introducing an arterial catheter.

Figure 56.10 Arterial occlusion just above the knee causing claudication of the calf; good collateral circulation (arteriogram by the Seldinger technique).

Non-surgical management of arterial stenosis or occlusion

General

For many patients with claudication, stopping smoking and regular exercise (walking) will lead to improvement of symptoms over the first six months as collaterals develop. Walking regularly within the limits of the disability is ideal; there is nothing to be gained from walking in pain. Supervised exercise programmes, dietary advice, and weight loss in obese patients, will help. If this advice is followed, the risk of progression to critical leg ischaemia and amputation is very small. Unfortunately, claudication is often a marker of silent coronary and cerebral arterial disease and 50 per cent of claudicants will

Figure 56.11 Magnetic resonance angiogram showing a tight stenosis at the midpoint of the left common iliac artery.

die within ten years from myocardial infarction or stroke. Patients with rest pain or tissue necrosis require urgent revascularisation to prevent limb loss.

Drugs

Medication may be required for diseases associated with arterial disorders, such as hypertension and diabetes; some antihypertensives (particularly β -blockers) may exacerbate claudication. Raised blood lipids require active drug treatment, but even when the lipid profile is normal, a statin should be prescribed as they may stabilise atherosclerotic plaques and protect against cardiac death. An antiplatelet agent is also necessary, usually 75 mg/day of aspirin, with 75 mg/day of clopidogrel as an alternative for those who are aspirin intolerant. Other agents, such as vasodilators, are unlikely to prove beneficial. Drugs are now available to help with smoking cessation.

Transluminal angioplasty and stenting

Arterial occlusive disease may be treated by inserting a balloon catheter into an artery and inflating it within a narrowed or blocked area (Figures 56.12 and 56.13). This technique is suitable for patients with claudication, rest pain or tissue necrosis, and is usually done in the radiology department (Figures 56.14 and 56.15). The basic method involves percutaneous femoral artery puncture under local anaesthetic followed by insertion of a guidewire which is negotiated through the stenosis or occlusion under fluoroscopic control. A balloon catheter is then inserted over the guidewire and positioned within the lesion. The balloon is then inflated at high pressure for approximately 1 minute and deflated. Satisfactory dilation of the lesion is confirmed by performing an angiogram. Percutaneous transluminal angioplasty (PTA) has proved very successful in dilating the iliac and femoropopliteal segments; the results below the knee are less successful. Long occlusions may be treated by the technique of subintimal angioplasty where the guidewire crosses the lesion in the subintimal space (in the arterial wall) and a new lumen is created by inflation of the balloon. Complications occur in about

Figure 56.12 Balloon catheter for percutaneous transluminal angioplasty.

Figure 56.13 (a) Catheter balloon deflated; (b) balloon inflated.

5 per cent of cases and include failure, haematoma, bleeding, thrombosis and distal embolisation.

If the vessels fail to stay adequately dilated (often caused by elastic recoil of the artery), it may be possible to hold the lumen open using a metal stent (Figures 56.16 and 56.17). This may be

Figure 56.14 Narrowed superficial femoral artery before and after transluminal angioplasty (courtesy of J McIvor, FRCR, London, UK). The advantage of this technique is that it can be carried out under local anaesthesia using the Seldinger technique of percutaneous arterial puncture, and is therefore especially useful in the treatment of patients who are medically unfit for major surgery.

introduced on a balloon catheter and expanded by balloon inflation; or alternatively a self-expanding stent may be used which is contained inside a plastic sheath and deployed by withdrawal of the sheath.

Figure 56.16 (a) Balloon catheter carrying stent; (b) expanded stent.

Operations for arterial stenosis or occlusion

Site of disease and type of operation

Surgical operations are usually reserved for patients with severe symptoms where angioplasty has failed or is not possible. Aortoiliac occlusion responds well to aortofemoral bypass

Figure 56.15 Before (a) and after (b) balloon dilatation of a severely stenosed left renal artery in a 20-year-old woman with uncontrollable hypertension. The blood pressure fell to normal after the procedure. The stenosis was probably due to fibromuscular hyperplasia, but no tissue was available for histological diagnosis.

Figure 56.17 (a) External iliac artery stenosis before dilatation; (b) after dilatation by percutaneous transluminal angioplasty; and (c) dilated artery patency assured by stent (courtesy of Johnson and Johnson Interventional Systems, Bracknell, UK, and Dr W Shaw, Ninewells Hospital, Dundee, UK).

(Figure 56.18a) using a Dacron graft (Figure 56.19a); although the operation carries a mortality rate of about 5 per cent. In unfit patients, an axillofemoral bypass is an alternative although patency rates are less. If only one iliac system is occluded, an iliofemoral or femorofemoral crossover graft may be performed.

Superficial femoral artery disease can be treated by femoropopliteal bypass (Figure 56.18b); long-term graft patency is determined by the quality of inflow and outflow, graft length (whether the distal anastomosis is above or below the knee) and

the conduit used for the bypass. Autogenous saphenous vein gives the best results and can be used reversed or *in situ* after valve disruption. If the long saphenous vein is not available from either leg, short saphenous or arm veins may be used. If no vein is available, a prosthetic polytetrafluoroethylene (PTFE) graft may be employed (Figure 56.19b), although patency rates are less; many surgeons construct the lower anastomosis using a small collar of vein (Miller cuff) between the PTFE and the recipient artery, which may improve patency. Isolated common femoral artery or profunda disease can be treated with endarterectomy and patch (vein or prosthetic) or a short bypass in the groin.

Sometimes, in patients with critical leg ischaemia, the occlusion extends beyond the popliteal artery into the tibial vessels. Limb salvage can be attempted with a femorodistal bypass with success even more dependent on the state of the run-off vessel and the quality of the vein conduit (minimum diameter 3 mm). The risk of early graft failure with limb loss is high and these long bypasses are only appropriate for limb salvage.

Technical details

For aortofemoral bypass, the aorta is approached through a midline or transverse abdominal incision. The common femoral arteries and their branches are exposed through vertical groin incisions. The small bowel is retracted to the right and the posterior peritoneum opened. Retroperitoneal tunnels are made from the aorta to the groins. Heparin (5000 U) is given intravenously and the vessels clamped. A vertical incision is made in the anterior aspect of the aorta to which an obliquely cut, bifurcated

Figure 56.18 (a) Atherosclerotic narrowing of the aortic bifurcation. Aortobifemoral graft to bypass stenosis. (b) Superficial femoral artery occlusion. Femoropopliteal graft used to bypass the occluded area into good 'run off' below.

Dacron graft is sutured end-to-side. The graft limbs are then fed down to the groins where they are anastomosed end-to-side to the common femoral arteries or, if there is evidence of profunda stenosis, to an arteriotomy running from the common femoral vessel down into the profunda. The posterior peritoneum is closed over the Dacron to prevent adhesion of the graft to bowel, and the abdomen and groin wounds are closed.

For femoropopliteal bypass, the popliteal artery above or below the knee is exposed through a medial incision. The common femoral artery is exposed at groin level. The long saphenous vein may be used in two different ways. First, it may be excised, its tributaries tied, and the vein used in a reversed fashion so the valves do not obstruct the flow of blood. Alternatively, it may be left in place (*in situ*) and the valves disrupted with a valvulotome. The graft is sutured to the femoral artery proximally and to the popliteal artery distally. Femorodistal bypass involves

Figure 56.19 (a) Dacron bifurcation graft; (b) polytetrafluoroethylene graft.

fashioning the distal anastomosis to a tibial vessel. If no suitable vein is available, prosthetic material (usually PTFE) may be used, with or without a small vein collar (Miller cuff) at its distal end (Figure 56.20a,b).

A femorofemoral crossover graft involves tunnelling a prosthetic graft subcutaneously above the pubis between the groins. An axillofemoral graft is tunnelled subcutaneously between the axillary artery proximally, to reach one or both of the femoral arteries; the patency rates of an axillobifemoral bypass is better than an axillo(uni)femoral bypass.

Results of operation

Long-term results of aortoiliac reconstructive surgery are good, usually marred only by progressive infrainguinal disease. Femoropopliteal surgery is less successful. Immediate postoperative success for vein bypass exceeds 90 per cent, but the five-year patency is around 60 per cent. PTFE bypass yields poorer results than vein bypass, with five-year success rates of less than 50 per cent. Although the results of femorodistal bypass are even less satisfactory, such surgery can ensure limb salvage in patients who are generally debilitated and whose expected lifespan is limited; long-term patency is less important.

Other sites of atheromatous occlusive disease

The principles of arterial surgery outlined above can be applied at other arterial sites. Carotid stenosis (at the carotid bifurca-

Figure 56.20 (a) Completion angiogram of femoropopliteal bypass graft (with Miller cuff). (b) Completion angiogram of femorodistal bypass graft *in situ*.

tion in the neck) may cause transient ischaemic attacks (TIA). These short-lived mini-strokes are often recurrent and cause unilateral motor or sensory loss in the arm, leg or face, transient blindness (amaurosis fugax) or speech impairment. They are caused by distal embolisation of platelet thrombi that form on the atheromatous plaque into the cerebral circulation. They are a warning of impending major stroke. Patients should be assessed with a duplex scan. If a tight stenosis (>70 per cent) is detected, carotid endarterectomy should be offered (Figure 56.21). Current guidelines for carotid endarterectomy are listed in Summary box 56.2. This involves clamping the vessels, an arteriotomy in the common carotid artery continued up into the internal carotid artery through the diseased segment, removal of the occlusive disease (endarterectomy) and closure of the arteriotomy, often with a patch. Many surgeons also use a temporary shunt to maintain cerebral blood flow while the carotid system is clamped.

Summary box 56.2

Indications for carotid endarterectomy in symptomatic patients

70% or greater carotid stenosis and:

- Ipsilateral amaurosis fugax or monocular blindness
- Contralateral facial paralysis or paraesthesia
- Arm/leg paralysis or paraesthesia
- Hemianopia
- Dysphasia (if dominant hemisphere)
- Sensory or visual inattention/neglect

Subclavian artery stenosis may cause claudication in the arm or digital ischaemia from distal embolisation. It may be treated by angioplasty or surgical bypass. Sometimes subclavian artery lesions are associated with neck pathology, such as a cervical rib which should be removed during arterial repair (see Chapter 57, Figure 57.37). Subclavian steal syndrome may occur if the first part of the subclavian artery is occluded. Arm exercise causes syncope because of reversed flow in the vertebral artery leading to cerebral ischaemia. It can be treated by angioplasty or surgery and is rare.

Mesenteric artery occlusive disease may cause pain after eating (intestinal angina) and weight loss. In general, two of the three enteric vessels (coeliac axis, superior mesenteric artery, inferior mesenteric artery) must be occluded to produce symptoms and other intestinal disorders must be excluded before treatment with PTA, endarterectomy or bypass.

Renal artery stenosis may cause hypertension and eventual renal failure. Although it is possible to improve renal blood flow with PTA or surgery, the mainstay of treatment is drugs to control hypertension, diabetes, etc.

GANGRENE

Gangrene refers to death of macroscopic portions of tissue which turn black because of the breakdown of haemoglobin and the formation of iron sulphide. It usually affects the most distal part of a limb because of arterial obstruction (from thrombosis, embolus or arteritis). Dry gangrene occurs when the tissues are desiccated by gradual slowing of the bloodstream; it is typically

Figure 56.21 Carotid stenosis. A unilateral localised stenosis suitable for operation. CC, common carotid; EC, external carotid; IC, internal carotid.

the result of atheromatous occlusion of arteries. Wet gangrene occurs when superadded infection and putrefaction are present. Crepitus may be palpated as a result of infection by gas-forming organisms commonly in diabetic foot problems.

Separation of gangrene

A zone of demarcation between the truly viable and the dead or dying tissue will eventually appear. Separation is achieved by the development of a layer of granulation tissue, which forms between the dead and the living parts. In dry gangrene, if the blood supply of the proximal tissues is adequate, the final line of demarcation appears in a matter of days and separation occurs neatly and with the minimum of infection. If bone is involved, complete separation takes longer than when soft tissues alone are affected, and the stump tends to be conical as the bone has a better blood supply than its coverings. In moist gangrene, the infection and suppuration extends into the neighbouring living tissue, causing the final line of demarcation to be more proximal than in dry gangrene.

If the arterial supply to the proximal living tissue is poor, the line of final demarcation is very slow to form or does not develop at all. Unless the arterial supply can be improved, the gangrene

will spread to adjacent tissues or will suddenly appear as 'skip' areas further up the limb. These skip lesions may occur on the other side of the foot, on the heel, on the dorsum of the foot or even in the calf. Infection may also cause gangrene to spread proximally into areas of extensive inflammation. To attempt local amputation in the presence of poor circulation will fail and gangrene will reappear in the wound or skin edges.

Treatment of gangrene

How much of a limb or digit can be salvaged depends on the blood supply proximal to the gangrene. Poor circulation can sometimes be improved by radiological or surgical intervention and this may allow a more conservative debridement or distal amputation. However, major limb amputation may be required in the presence of life-threatening sepsis, when the blood supply cannot be improved or in patients whose limb is useless because of contractures, stroke, etc.

Specific varieties of gangrene

Diabetic gangrene

Diabetic gangrene is usually caused by a combination of three factors – ischaemia secondary to atheroma, peripheral neuropathy which leads to trophic skin changes and immunosuppression caused by excess of sugar in the tissues which predisposes to infection (Figure 56.22). The neuropathy is usually sensory which favours the neglect of minor injuries and infections. Motor involvement is frequently accompanied by loss of reflexes and deformities (neuropathic joints). Thick callosities develop on the sole of the foot which together with poor chiropody may allow the entry of infection that can spread rapidly and proximally in subfascial planes. Treatment depends on the degree of arterial involvement which should be investigated and treated rapidly with angioplasty or surgery. The gangrene is treated by drainage of pus, debridement of dead tissue with local amputation of necrotic digits and antibiotics.

Bedsore

A bedsore is gangrene caused by local pressure (Figure 56.23). Bedsore are predisposed to by five factors: pressure, injury, anaemia, malnutrition and moisture. They can appear and extend rapidly in immobile patients and in those with debili-

Figure 56.22 Diabetic gangrene.

Figure 56.23 Bedsores typically appear over areas exposed to pressure, such as the sacrum and (as in this case) the heel.

tating illness. Prophylactic measures must be taken, including the avoidance of pressure over bony prominences by the use of foam blocks or similar, regular turning, and nursing on specially designed beds that reduce the pressure to the skin. A water bed or a ripple bed is sometimes desirable. Injury from wrinkled sheets and maceration of the skin by sweat, urine, faeces or pus must be prevented by skilled nursing and the use of appropriate dressings.

A bedsore can be expected if erythema appears that does not change colour on pressure. Once pressure sores develop, they are difficult to heal. They should be kept clean and debrided if necessary. Advice from a plastic surgeon should be sought for major lesions; vacuum dressings and rotation flaps can be effective.

Frostbite

Frostbite is caused by exposure to cold. It is seen both in climbers at high altitudes and in the elderly or the vagrant during cold weather (Figure 56.24). Cold injury damages the wall of the blood vessel which causes swelling and leakage of fluid together with severe pain. When the pain disappears, a waxy appearance remains; blistering and then gangrene follow. Treatment is gradual rewarming, analgesics and delayed conservative amputation after demarcation of devitalised tissue.

ACUTE ARTERIAL OCCLUSION

Sudden occlusion of an artery is usually caused by an embolus. It may also happen when thrombosis occurs on an atherosclerotic plaque, although the outcome is usually less dramatic because collaterals are likely to have developed in chronic arterial stenosis.

Embolic occlusion

An embolus is a body that is foreign to the bloodstream and which may become lodged in a vessel and cause obstruction. It is often a thrombus that has become detached from the heart or a more proximal vessel. Sources include the left atrium in atrial fibrillation, a left ventricular mural thrombus following myocardial infarction; vegetations on heart valves in infective endocarditis, thrombi in aneurysms and on atherosclerotic plaques. Emboli may lodge in any organ and cause ischaemic symptoms.

- **Arm and leg.** Pain, pallor, paralysis, pulselessness and paraesthesia (Figure 56.25). Acute arterial occlusion due to an embolus differs from occlusion due to thrombosis on pre-existing atheroma; in the latter case, a collateral circulation has often built up over time (Figures 56.26 and 56.27). It is essential to differentiate between the two as they require different management.

Figure 56.24 (a) Frostbite of the foot. Note the clear demarcation. (b) Frostbite of the middle finger in the same patient. The index finger was lost two years before, also from frostbite.

Figure 56.25 The symptoms and signs of embolism (four Ps). The fifth feature, anaesthesia, is often stated to be paraesthesia (the fifth P) but, in truth, complete loss of sensation in the toes and feet is characteristic.

Figure 56.26 Aortic bifurcation embolus. Source of embolus is a recent myocardial infarct or atrial fibrillation. This causes severe, dramatic symptoms.

Figure 56.27 Aortic bifurcation thrombosis. No source of embolus but previous claudication. Claudication worse but no dramatic event.

- **Brain.** The middle cerebral artery (or its branches) is most commonly affected, resulting in major or minor (TIA) stroke.
- **Retina.** Amaurosis fugax is fleeting blindness caused by a minute thrombus emanating from an atheromatous plaque in the carotid artery passing into the central retinal artery. Lasting obstruction causes permanent blindness.

- **Mesenteric vessels.** Possible gangrene of the corresponding loop of intestine.

Acute limb ischaemia

Clinical features

Embolic arterial occlusion is an emergency that requires immediate treatment. Ischaemia beyond 6 hours is usually irreversible and results in limb loss. The leg is often affected, with pain, pallor, paralysis, loss of pulsation and paraesthesia (or anaesthesia) (Figure 56.25). The limb is cold and the toes cannot be moved, which contrasts with venous occlusion when muscle function is not affected. The diagnosis can be made clinically in a patient who has no history of claudication and has a source of emboli, who suddenly develops severe pain or numbness of the limb, which becomes cold and mottled. Movement becomes progressively more difficult and sensation is lost. Pulses are absent distally, but the femoral pulse may be palpable, even thrusting, as distal occlusion results in forceful expansion of the artery with each pressure wave despite the lack of flow. A similar picture will occur in the arm with a brachial embolus.

Treatment

Because of the ensuing stasis, a thrombus can extend distally and proximally to the embolus. The immediate administration of 5000 U of heparin intravenously can reduce this extension and maintain patency of the surrounding (particularly the distal) vessels until the embolus can be treated. The relief of pain is essential because it is severe and constant. Embolectomy and thrombolysis are the treatments available for patients with limb emboli.

Embolectomy

Local or general anaesthesia may be used. The artery (usually the femoral), bulging with clot, is exposed and held in slings. Through a longitudinal or transverse incision, the clot begins to extrude and is removed, together with the embolus (Figure 56.28), with the help of a Fogarty balloon catheter. The catheter, with its balloon tip, is introduced both proximally and distally until it is deemed to have passed the limit of the clot. The

Figure 56.28 Embolic material removed from the common femoral artery, along with a long distal extension thrombus.

Thomas J Fogarty, born 1934, surgeon, University of Oregon Medical School, Portland, OR, USA. Since 1993, Professor of Surgery, Stanford University, CA, USA; patented his catheter in 1969; first balloon angioplasty performed with a Fogarty catheter in 1965; recipient of Inventor of the Year Award given by San Francisco Patent and Trademark Association. He became very interested in wine and established the Thomas Fogarty Winery and Vineyards in California in 1981.

balloon is inflated and the catheter withdrawn slowly, together with any obstructing material (Figure 56.29). The procedure is repeated until back bleeding occurs. An angiogram may be performed in the operating theatre at the end of the procedure to ensure that flow to the distal leg has been restored. Postoperatively, heparin therapy is continued until long-term anticoagulation with warfarin is established to reduce the chance of further embolism.

Compartment syndrome

In limbs that have been subject to sudden ischaemia followed by revascularisation, oedema is likely. Muscles swell within fixed fascial compartments and this can itself be a cause of ischaemia, with both local muscle necrosis and nerve damage due to pressure, and distal effects such as renal failure secondary to the liberation of muscle breakdown products. The treatment is urgent fasciotomy to release the compression. The usual site for fasciotomy is the calf (especially the anterior tibial compartment), but compartment syndrome may occasionally affect the thigh and the arm.

Intra-arterial thrombolysis

If ischaemia is not so severe that immediate operation is essential, it may be possible to treat either embolus or thrombosis by intra-arterial thrombolysis (Figure 56.30). At arteriography of the ischaemic limb (usually via the common femoral artery), a narrow catheter is passed into the occluded vessel and left embedded within the clot. Tissue plasminogen activator (TPA) is infused through the catheter and regular arteriograms are carried out to check on the extent of lysis, which, in successful cases, is achieved within 24 hours. The method should be abandoned if there is no progression of dissolution of clot with time. There are several contraindications to thrombolysis, the most important of which are recent stroke, bleeding diathesis and pregnancy, and results in those over 80 years old are poor.

Figure 56.29 (a) A Fogarty catheter is inserted through an arteriotomy in the common femoral artery and fed distally down the superficial femoral artery and through the embolus. (b) The balloon is inflated and the catheter withdrawn, removing the embolus; the deep femoral and iliac arteries are similarly treated.

Figure 56.30 Angiogram of an occluded popliteal artery before thrombolysis (left), during successful lysis (middle) and after completion of lysis (right).

Acute mesenteric ischaemia

Acute mesenteric occlusion may be either thrombotic (following atheromatous narrowing) or embolic. Embolic occlusion results in sudden, severe abdominal pain, with bowel emptying (vomiting and diarrhoea) and a source of emboli present (usually cardiac). Unfortunately, the diagnosis is often only made at laparotomy with widespread infarction of the small and large bowel present; in this situation, it is fatal. Occasionally, the degree of bowel infarction is more limited; resection of the dead bowel and embolectomy of the superior mesenteric artery, or bypass surgery can reduce the otherwise high mortality rate in these patients. A 'second look' laparotomy 24 hours later to check the viability of the bowel is often indicated.

Other forms of emboli

Infective emboli of bacteria or an infected clot may cause mycotic aneurysms, septicaemia or infected infarcts. Parasitic emboli, caused by the ova of *Taenia echinococcus* and *Filaria sanguinis hominis*, may occur in some countries. Tumour cells (e.g. hypernephroma and cardiac myxoma) are rare causes of emboli. Fat embolism may follow major bony fractures. However, it usually causes venous emboli that travel to the lungs and cause acute respiratory distress syndrome.

Air embolism

Air may be accidentally injected into the venous circulation or sucked into an open vein during head and neck surgery or a cut throat. It may also occur following Fallopian tube insufflation or illegal abortion. If a large volume of air reaches the right side of the heart it may form an air lock within the pulmonary artery and cause acute right heart failure.

The treatment of air embolism is to put the patient in a head-down (Trendelenburg) position to encourage the air to enter the veins in the lower part of the body. The patient should also be placed on the left side to help the air to float to the ventricular apex, away from the ostium of the pulmonary artery. In extreme

cases, air may be aspirated from the heart through a needle introduced below the left costal margin.

Therapeutic embolisation

This is used to arrest haemorrhage from the gastrointestinal, urinary (Figure 56.31), gynaecological and respiratory tracts, to treat arteriovenous malformations by blocking their arterial supply and to control the growth of unresectable tumours. Arterial embolisation requires accurate selective catheterisation using the Seldinger technique. A variety of materials may be used, including gelfoam sponge, plastic microspheres, balloons, ethyl alcohol, quick-setting plastics and metal coils.

AMPUTATION

General

Amputation should be considered when part of a limb is dead, deadly or a dead loss. A limb is dead when arterial occlusive disease is severe enough to cause infarction of macroscopic portions of tissue, i.e. gangrene. The occlusion may be in major vessels (atherosclerotic or embolic occlusions) or in small peripheral vessels (diabetes, Buerger's disease, Raynaud's disease, inadvertent intra-arterial injection). If the obstruction cannot be reversed and the symptoms are severe, amputation is required.

A limb is deadly when the putrefaction and infection of moist gangrene spreads to surrounding viable tissues. Cellulitis and severe toxæmia are the result. Amputation is required as a life-saving operation. Antibiotic cover should be broad and massive. Other life-threatening situations for which amputation may be required include gas gangrene (as opposed to simple infection), neoplasm (such as osteogenic sarcoma) and arteriovenous fistula.

Figure 56.31 Before (a) and after (b) therapeutic embolisation of the internal iliac artery in a patient with gross haematuria from an ulcerating bladder carcinoma (courtesy of F McIvor, FRCR, London, UK).

A limb may be deemed a dead loss in the following circumstances: first, when there is relentless severe rest pain without gangrene and reconstruction is not possible – amputation will improve quality of life; second, when a contracture or paralysis makes the limb impossible to use and renders it a hindrance; and third, when there is major unrecoverable traumatic damage (Summary box 56.3).

Summary box 56.3

Indications for amputation

- Dead limb
 - Gangrene
- Deadly limb
 - Wet gangrene
 - Spreading cellulitis
 - Arteriovenous fistula
 - Other (e.g. malignancy)
- 'Dead loss' limb
 - Severe rest pain with unreconstructable critical leg ischaemia
 - Paralysis
 - Other (e.g. contracture, trauma)

Distal and transmetatarsal amputation

In patients with small-vessel disease, typically caused by diabetes, gangrene of the toes may occur with relatively good blood supply to the surrounding tissues. In such circumstances, local amputation of the digits can result in healing. However, if the metatarsophalangeal joint region is involved, a ray excision is required, taking part of the metatarsal and cutting tendons back. Most surgeons leave the wound open. Early mobility aids drainage provided that cellulitis is not present. For less extensive gangrene, if amputation is taken through a joint, healing is improved by removing the cartilage from the joint surface. A transmetatarsal amputation may be required when several toes are affected, but the proximal circulation is adequate. The wound may be closed with a viable long plantar flap (Figure 56.32) or left open.

Major amputation

Choice of operation

The major choice is between an above- or below-knee operation. A below-knee amputation preserves the knee joint and gives the best chance of walking again with a prosthesis. However, an above-knee amputation is more likely to heal and may be appropriate if the patient has no prospect of walking again. If the femoral pulse is absent, the amputation should be above the knee. Unfortunately, the presence of a femoral pulse does not guarantee healing of a below-knee amputation and sometimes a

Sir William Ferguson (1808–1877), surgeon, Royal Infirmary, Edinburgh, later Professor of Surgery, King's College Hospital, London, said that amputation is 'one of the meanest, and yet one of the greatest operations in surgery: mean, when resorted to where better may be done – great, as the only step to give comfort and prolong life'.

Sir Edward 'Weary' Dunlop, a great Australian surgeon. During the Second World War, as a prisoner of war (POW) held by the Japanese while looking after other POWs working on the Burma–Siam Railway, he made prosthetic lower limbs for amputees out of bamboo.

Figure 56.32 Transmetatarsal amputation for diabetic gangrene of the toes.

Figure 56.33 Classic long posterior flap type of below-knee amputation.

failed below-knee amputation may require revision to an above-knee procedure.

For above- or below-knee amputations with a good stump shape, it is possible to hold a prosthesis in place simply by suction, without any cumbersome and unsightly straps. The stump should be of sufficient length to give the required leverage, i.e. not less than 8 cm below the knee (preferably 10–12 cm) and not less than 20 cm above the knee.

Below-knee amputations

Two types of skin flap are commonly used: long posterior flap and skew flap (described by KP Robinson). For both methods, the total length of flap must be at least one and a half times the diameter of the leg at the point of bone section.

The long posterior flap technique is the older method and remains the more popular probably because of its relative simplicity (Figure 56.33). Anteriorly, the incision is deepened to bone and the lateral and posterior incisions are fashioned to leave the bulk of the gastrocnemius muscle attached to the flap, muscle and skin being transected together at the same level. If bleeding is inadequate, the amputation is refashioned at a higher level. Blood vessels are identified and ligated. Nerves are not clamped, but pulled down gently and transected as high as possible. Vessels in nerves are ligated. The fibula is divided 2 cm proximal to the level of tibial division using bone cutters. The tibia is cleared and transected at the desired level, the anterior aspect of the bone being sawn obliquely before the cross-cut is made. This, with filing, gives a smooth anterior bevel, which

prevents pressure necrosis of the flap. The long muscle/skin flap is tapered after removing the bulk of the soleus muscle (much of the gastrocnemius may be left, unless it is very bulky). The area is washed with saline to remove bone fragments and the muscle and fascia are sutured with an absorbable material to bring the flap over the bone ends. A suction drain is placed deep to the muscle and brought out through a stab incision in the skin. The skin flap should lie in place with all tension taken by the deep sutures. Interrupted skin sutures are inserted. Gauze, wool and crepe bandages are usually used for the stump dressing.

The skew flap amputation makes use of anatomical knowledge of the skin blood supply. Equally long flaps are developed; they join anteriorly 2.5 cm from the tibial crest, overlying the anterior tibial compartment, and posteriorly at the exact opposite point on the circumference of the leg. After division of bone and muscle in a fashion similar to that described above, the gastrocnemius flap is sutured over the cut bone end to the anterior tibial periosteum with absorbable sutures. Finally, drainage and skin sutures are inserted and the limb dressed as for the long posterior flap operation.

Above-knee amputation

The site is chosen as indicated above, but may need to be higher if bleeding is poor on incision of the skin. Equal curved anterior and posterior skin flaps are made of sufficient total length. Skin, deep fascia and muscle are transected in the same line. Vessels are ligated. The sciatic nerve is pulled down and transected cleanly as high as possible and the accompanying artery ligated.

James Syme, 1799–1871, Regius Professor of Clinical Surgery, University of Edinburgh, Edinburgh, UK.

Rocco Grilli, 1828–1920, surgeon, Milan, Italy, described this operation in 1857.

Sir William Stokes, 1839–1900, surgeon, Dublin, Ireland described his modification of Grilli's operation in 1870.

Kingsley Peter Robinson, formerly surgeon, The Westminster Hospital, London, UK

Muscle and skin are retracted and the bone cleared and sawn at the point chosen. Haemostasis is achieved. The muscle ends are united over the bone by absorbable sutures incorporating the fascia. A suction drain deep to the muscle is brought out through the skin clear of the wound. The fascia and subcutaneous tissues are further brought together so that the skin can be apposed by interrupted sutures. Gauze, wool and crepe bandages form the stump dressing.

Postoperative care of an amputee

Opiate pain relief should be given regularly. Care of the good limb must not be forgotten as a pressure ulcer on the remaining foot will delay mobilisation, despite satisfactory healing of the stump. Exercise and mobilisation are of the greatest importance. After surgery, flexion deformity must be prevented and exercises started to build up muscle power and coordination. Mobility is progressively increased with walking between bars and the use of an inflatable artificial limb, which allows weight-bearing to be started before a pylon or temporary artificial limb is ready (Figure 56.34). Early assessment of the home is part of the programme; it allows time for minor alterations, such as the addition of stair rails, movement of furniture to give support near doors and provision of clearance in confined passages.

Complications

Early complications include haemorrhage (which requires return to the operating theatre for haemostasis), haematoma (which requires evacuation) and infection (usually in association with a haematoma). Any abscess must be drained and appropriate antibiotics given. Gas gangrene can occur in a mid-thigh stump from faecal contamination. Wound dehiscence and gangrene of the flaps are caused by ischaemia; a higher amputation may be necessary. Amputees are at risk of deep vein thrombosis

Figure 56.34 Inflatable artificial limb.

and pulmonary embolism in the early postoperative period and prophylaxis with subcutaneous heparin is essential.

Later complications include pain resulting from unresolved infection (sinus, osteitis, sequestrum), a bone spur, a scar adherent to bone and an amputation neuroma. Patients frequently remark that they can feel the amputated limb (phantom limb) and sometimes remark that it is painful (phantom pain). The surgeon's attitude should be one of firm reassurance that this sensation will almost certainly disappear with time; amitriptyline or gabapentin may help. Other late complications include ulceration of the stump because of pressure effects of the prosthesis or increased ischaemia.

ANEURYSM

General

Dilatations of localised segments of the arterial system are called 'aneurysms'. They can either be true aneurysms, containing the three layers of the arterial wall (intima, media, adventitia) in the aneurysm sac, or false aneurysms, having a single layer of fibrous tissue as the wall of the sac, e.g. aneurysm following trauma. Aneurysms can also be grouped according to their shape (fusiform, saccular) or their aetiology (atheromatous, traumatic, mycotic, etc.). The term 'mycotic' is a misnomer because, although it indicates infection as the cause of the aneurysm, it is due to bacteria, not fungi. Aneurysms may occur in the aorta, iliac, femoral, popliteal, subclavian, axillary, carotid, cerebral, mesenteric, splenic and renal arteries and their branches. The majority are true fusiform atherosclerotic aneurysms (Summary box 56.4).

Summary box 56.4

Classification of aneurysms

- Wall
 - True (three layers: intima, media, adventitia)
 - False (single layer of fibrous tissue)
- Morphology
 - Fusiform
 - Saccular
- Aetiology
 - Atheromatous
 - Mycotic (bacterial rather than fungal)
 - Collagen disease
 - Traumatic

Clinical features

All aneurysms can cause symptoms, as a result of compression of surrounding structures, thrombosis, rupture or the release of emboli. The symptoms relate to the vessel affected and the tissues it supplies. Many aneurysms of clinical significance can be palpated and, typically, an expansile pulsation is felt. Transmitted pulsation through a mass lesion, cyst or abscess lying adjacent to a large artery may be mistaken for aneurysmal pulsation. Before incising a swelling believed to be an abscess, it is essential to make sure that it does not pulsate. Finally, a tortuous (and often ectatic) artery, usually the innominate or carotid, may seem like an aneurysm to the inexperienced clinician.

Abdominal aortic aneurysm

Abdominal aortic aneurysm is by far the most common type of large vessel aneurysm and is found in 2 per cent of the population at autopsy; 95 per cent have associated atheromatous degeneration and 95 per cent occur below the renal arteries. Most remain asymptomatic until rupture occurs; the risk of rupture increases with increasing size (diameter) of the aneurysm. Asymptomatic aneurysms are found incidentally on physical examination, radiography or ultrasound investigation. It may be appropriate to screen for abdominal aortic aneurysms with ultrasound; a national screening programme has recently started in England and offers an ultrasound scan to men in their 65th year. Symptomatic aneurysms may cause minor symptoms, such as back and abdominal discomfort, before sudden, severe back and/or abdominal pain develops from expansion and rupture.

Asymptomatic abdominal aortic aneurysm

An asymptomatic abdominal aortic aneurysm (Figure 56.35) in an otherwise fit patient should be considered for repair if >55 mm in diameter (measured by ultrasonography). The annual incidence of rupture rises from 1 per cent or less in aneurysms that are <55 mm in diameter to a significant level, perhaps

Figure 56.35 Ultrasonogram of an aortic aneurysm showing the large clot-filled sac with a small central lumen (a) transverse and (b) longitudinal scans.

as high as 20 per cent, in those that are 70 mm in diameter. Assuming open elective surgery (transabdominal) carries a 5 per cent mortality rate, the balance is in favour of elective operation once the diameter is >55 mm, provided there is no major comorbidity. Regular ultrasonographic assessment is indicated for asymptomatic aneurysms <55 mm in diameter.

Investigations

Full blood count, electrolytes, liver function tests, coagulation tests and blood lipid estimation should be performed. Blood should be crossmatched a few days prior to surgery. Many patients now have an anaesthetic assessment and the need for cardiac and respiratory function tests are decided at this time. An electrocardiogram and chest radiograph are essential; further assessment may include echocardiography or isotope ventriculography, cardiopulmonary exercise testing and spirometry.

The morphology of the aneurysm is best assessed by CT scan (Figures 56.36 and 56.37). Fifty per cent of aneurysms are suitable for endovascular (minimally invasive) repair usually via the femoral arteries in the groin. If lower limb pulse is absent, there may be associated arterial occlusive disease which should be assessed by duplex scanning initially. Further assessment with CT, MR or digital subtraction angiography may be required and angioplasty may be appropriate. The aneurysm is often filled with circumferential clot (Figure 56.38a), which produces a falsely narrowed appearance on digital subtraction angiography (Figure 56.38b); this method should not therefore be used to assess aneurysm size.

Choice of operation – open or endovascular repair

Open surgical procedure

Under general anaesthesia, with the patient lying supine, a full-length midline or supraumbilical transverse incision is made. The small bowel is lifted to the patient's right and the aorta identified. The posterior peritoneum overlying the aorta is opened and the upper limit of the aneurysm identified. The aorta immediately above the dilatation is exposed; this is generally just inferior to the left renal vein and renal arteries (Figure 56.39).

Figure 56.36 Computed tomogram of the abdomen showing an aortic aneurysm. Blood flowing through the thrombus-containing sac is enhanced by intravascular contrast and therefore appears white while the thrombus remains unenhanced.

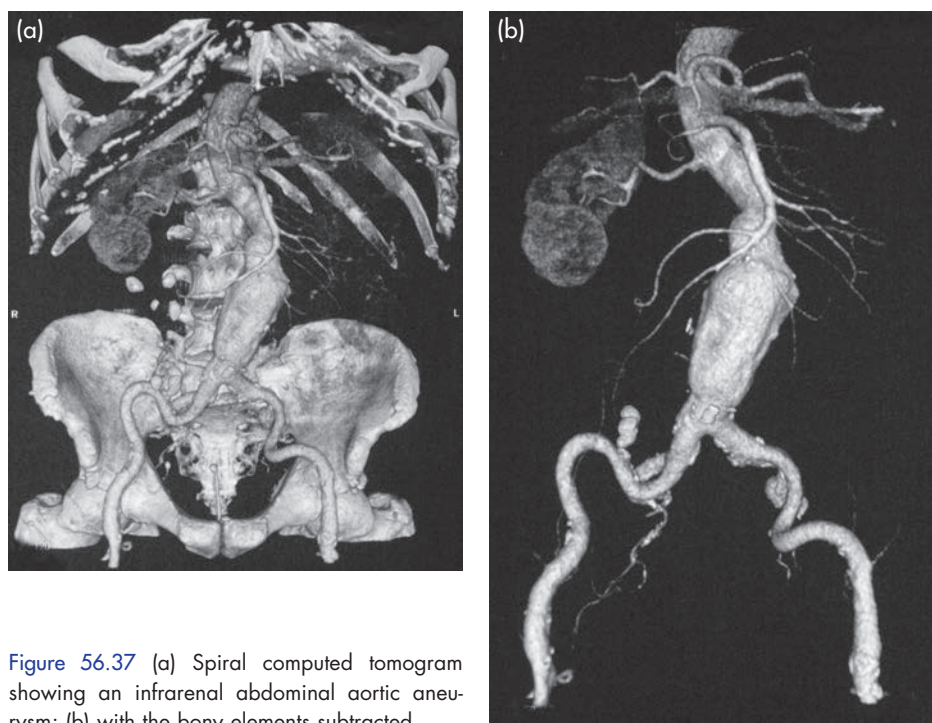

Figure 56.37 (a) Spiral computed tomogram showing an infrarenal abdominal aortic aneurysm; (b) with the bony elements subtracted.

Figure 56.38 (a) Thrombus removed from an abdominal aortic aneurysm; this thrombus is the reason an angiogram may give a false impression of aneurysm diameter on digital subtraction angiography (b).

Figure 56.39 Operative appearance of a huge, non-ruptured infrarenal abdominal aortic aneurysm.

The common iliac arteries are then exposed and clamps applied above and below the lesion. Many surgeons give systemic heparin before clamping. The aneurysm is opened longitudinally and back-bleeding from lumbar and mesenteric vessels controlled by sutures placed from within the sac. Upper and lower aortic necks are prepared to which an aortic prosthesis is then sutured end to end inside the sac with a monofilament non-absorbable suture (Figure 56.40). Clamps are released slowly to prevent sudden hypotension. If haemostasis is satisfactory at this point, the aneurysm sac is closed around the prosthesis to exclude both it and the suture lines from the bowel to reduce the risk of adherence and potential fistula formation. The abdomen is then closed. Occasionally, when the iliac vessels are also involved with dilatation or severe atheroma, it is necessary to construct an aortobi-iliac or aortobifemoral bypass, rather than use a simple aorto-aortic tube.

Endovascular aneurysm repair

Endovascular aneurysm repair (EVAR) is now established in clinical practice and has been shown to have reduced mortality compared to open repair over the first six years. Currently, about 50 per cent of infrarenal aneurysms are suitable for EVAR which is dependent on the morphology of the aneurysm when

assessed by CT scan. Common causes of unsuitability include a short, flared or angulated neck and difficult iliac artery access because of narrowing or tortuosity. The usual technique is to expose both femoral arteries (under general or local anaesthetic) which allows access to the aorta. Then, under radiological control, guidewires and catheters are used to cross the aneurysm and an angiogram performed to mark the level of the renal arteries.

The endovascular prosthesis (often termed a 'stent graft') is usually made up of three separate parts – a main body (Figure 56.41a) and two limbs which are enclosed in separate delivery catheters (Figure 56.41b). Some types have only two pieces – a main body with ipsilateral limb attached and a separate contralateral limb. The prosthesis is made from Dacron or PTFE with integral metallic stents for support. The delivery catheter is inserted in the aneurysm sac and the stent graft deployed by withdrawal of the delivery system. Most systems now have hooks or barbs to anchor the prosthesis in the aortic wall and some surgeons inflate a moulding balloon catheter in the stent graft to ensure the hooks and barbs are engaged and a good seal is obtained (Figure 56.42). Although the top edge of the fabric of the stent graft has to be deployed below the renal arteries (infrarenal fixation), some systems have additional bare metal stents at the proximal end of the main body which lie across

Figure 56.40 (a) Aneurysm sac opened. Note that the posterior wall of the aorta immediately above and below the sac is not divided. A Dacron tube graft is laid in place within the sac ready for suture. (b) Graft sutured in place and vascular clamps removed.

Figure 56.41 (a) Endovascular prosthesis main body (b) with separate limbs.

Figure 56.42 Spiral computed tomogram showing an endoluminal aortoiliac 'stent graft'. The metallic stent structure is clearly observed.

the renal arteries to give better support and fixation (suprarenal fixation). Blood flows between the metal struts of the stent into the renal arteries. Success is dependent on a good seal between the stent graft and the proximal and distal 'landing zones' in the aorta and iliac arteries. Failure to achieve a good seal results in

an endoleak which means that the aneurysm is not excluded from the circulation and may still expand and rupture. Patients who undergo EVAR require life-long follow up and surveillance with duplex or CT scans to detect endoleak, disconnection of the components and migration of the stent graft, all of which predispose to late rupture (Figure 56.43).

Ruptured abdominal aortic aneurysm

Abdominal aortic aneurysms can rupture anteriorly into the peritoneal cavity (20 per cent) or posterolaterally into the retroperitoneal space (80 per cent). Less than 50 per cent of patients with rupture survive to reach hospital. Anterior rupture results in free bleeding into the peritoneal cavity; very few patients reach hospital alive. Posterior rupture on the other hand produces a retroperitoneal haematoma (Figure 56.44). Often a brief period ensues when a combination of moderate hypotension and the resistance of the retroperitoneal tissues arrests further haemorrhage and may allow transport to hospital. The patient may remain conscious, but in severe pain. If no operation is performed, death is virtually inevitable. Operative mortality is around 50 per cent and the overall combined mortality (community and hospital) is around 80–90 per cent.

Ruptured abdominal aortic aneurysm is a surgical emergency; it should be suspected in a patient with the triad of severe abdominal and/or back pain, hypotension and a pulsatile abdominal mass. If there is doubt about the presence of an aneurysm an ultrasound scan may help, but this cannot diagnose rupture. CT scanning is performed in an increasing number of patients to establish the diagnosis and to determine whether an endovascular repair is possible.

Good venous access is needed for infusion of saline or volume expanding fluids, but the systolic blood pressure should not be raised any more than is necessary to maintain consciousness and permit cardiac perfusion (<100 mmHg). Many surgeons now adopt a policy of permissive hypotension where fluids are withheld if the patient is conscious (and cerebral perfusion is therefore adequate), in order to avoid provoking further uncontrolled haemorrhage. After CT scanning, the patient should be transferred immediately to an operating theatre where a urinary

Figure 56.43 Duplex ultrasound scan post-endovascular aneurysm repair (EVAR) showing aortic sac in cross-section and two limbs of EVAR (red ovals). There is a type II endoleak from the inferior mesenteric artery with blood flowing retrogradely into the aneurysm sac (arrow).

Figure 56.44 The retroperitoneal haematoma of a ruptured aortic aneurysm. The aortic pulsation is palpated through the haematoma at its upper limit and fingers are insinuated on each side of the aorta. With finger control, the upper clamp is positioned and closed on the aorta. The procedure is then as for a planned case. In this illustration, the clamp is at the proximal end of the aneurysm; the haematoma has spread from the left paracolic gutter to encircle the aneurysm and the aortic bifurcation.

catheter and arterial line are usually inserted. If the patient appears stable, surgery may be delayed until cross-matched blood is available, but surgery should commence immediately if haemodynamic instability develops and the patient collapses. The abdomen is usually prepared and draped with the patient awake. It should always be remembered that the treatment of ruptured aneurysm is operation, not monitoring and resuscitation (Summary box 56.5).

Summary box 56.5

Management of ruptured abdominal aortic aneurysm

- Early diagnosis (abdominal/back pain, pulsatile mass, shock)
- Immediate resuscitation (oxygen, intravenous replacement therapy, central line)
- Maintain systolic pressure, but not >100 mmHg, consider permissive hypotension
- Urinary catheter
- Cross-match six units of blood
- Rapid transfer to the operating theatre

Symptomatic abdominal aortic aneurysm

These patients most commonly present with abdominal and/or back pain, but the aneurysm is not ruptured on CT scan. Pain may also occur in the thigh and groin because of nerve compression. Gastrointestinal, urinary and venous symptoms can also be caused by pressure from an abdominal aneurysm. About 3 per cent of all aneurysms cause pain as a result of inflammation of the aneurysm itself (Figure 56.45). Finally, a few cause symptoms from distal embolisation of fragments of their intraluminal thrombus. An operation is usually indicated in patients who are otherwise reasonably fit. Pain may be a warning sign of stretching of the aneurysm sac and imminent rupture; surgery should be performed as soon as possible (usually on the next available operating list). The operative mortality of symptomatic aneurysms is usually higher than elective cases.

Postoperative complications

The most common complications after open repair are cardiac (ischaemia and infarction) and respiratory (atelectasis and lower lobe consolidation). A degree of colonic ischaemia because of a lack of a collateral blood supply occurs in about 10 per cent of patients, but fortunately this usually resolves spontaneously. Renal failure is an uncommon event after elective procedures but may complicate procedures undertaken for rupture. Renal

Figure 56.45 An inflammatory abdominal aortic aneurysm. Note the white 'icing' effect. Such lesions can be technically difficult to manage.

failure is more likely if there is preoperative renal impairment or considerable intraoperative blood loss. Neurological complications include sexual dysfunction and spinal cord ischaemia. An aortoduodenal fistula is an uncommon but treatable complication of abdominal aortic replacement surgery. It should be suspected whenever haematemesis or melaena occurs in the months or years after operation. Prosthetic graft infection is also uncommon; it may require removal of the graft and limb revascularisation by insertion of an axillobifemoral bypass.

Cardiac, respiratory, renal and neurological complications are less common after endovascular repair. However, there are complications that are unique to EVAR such as endoleak, graft migration, metal strut fracture and graft limb occlusion. Life-long surveillance with duplex or CT (together with plain abdominal x-ray for strut fracture) is required to detect endoleak and migration. High pressure endoleaks may require repeat ballooning or a proximal cuff or distal limb extension to reseat the endograft. Migration may also require extension of the graft. Overall, 10–20 per cent of patients with EVAR will require secondary interventions to treat complications at some future date, although many of the interventions can be performed via a percutaneous approach via the femoral artery in the angiography suite.

Peripheral aneurysm

Popliteal aneurysm

Popliteal artery aneurysm accounts for 70 per cent of all peripheral aneurysms; two-thirds are bilateral. Examination of the abdominal aorta is indicated if a popliteal aneurysm is found because one-third are accompanied by aortic dilatation. Popliteal aneurysms present as a swelling behind the knee or with symptoms caused by complications, such as severe ischaemia following thrombosis or distal ischaemia as a result of emboli. The diagnosis is usually confirmed with duplex scanning, but assessment of the distal vessels (with CT, MR or DSA) is important prior to repair if the foot pulses are diminished or absent. An asymptomatic aneurysm should be considered for elective repair to prevent future complications, especially if it exceeds 25 mm in diameter. Some surgeons would also offer elective repair if the sac contained thrombus because this may predispose to distal emboli. Surgery usually involves a medial approach to the above and below knee popliteal arteries, ligation of the aneurysm and restoration of flow to the foot with a bypass graft using saphenous vein. An alternative is a posterior approach and an inlay graft.

In the acute situation, the presentation is usually with a thrombosed aneurysm and an ischaemic foot. Surgery is often unsuccessful because the distal vessels are thrombosed and difficult to clear. Attempts should be made with a Fogarty catheter and intra-arterial thrombolysis. The limb loss rate is high (50 per cent).

Femoral aneurysm

True aneurysm of the femoral artery is uncommon. Complications occur in less than 3 per cent so conservative treatment is generally indicated, but it is important to look for aneurysms elsewhere as over half are associated with abdominal or popliteal aneurysms. Large aneurysms should be repaired. False aneurysm of the femoral artery occurs in 2 per cent of patients after arterial surgery at this site. Local repair may involve reanastomosis of the bypass in the groin under suitable antibiotic cover. However, if

infection is the cause, the treatment may involve excision of the infected graft and insertion of a further bypass routed around the infected area. In the latter case, the failure rate is high, and limb loss may be unavoidable. For false aneurysms caused by femoral artery puncture, thrombin injection under ultrasound guidance may be successful and avoids surgery; the alternative is arterial repair and suturing the puncture site in the artery.

Iliac aneurysm

This usually occurs in conjunction with aortic aneurysm and only rarely on its own. On its own, it is difficult to diagnose clinically so about half present already ruptured. Open surgery usually involves an inlay graft, but some iliac aneurysms may be suitable for endovascular repair.

Arteriovenous fistula

Communication between an artery and a vein (or veins) may be either a congenital malformation or the result of trauma. Arteriovenous fistulae for haemodialysis access are also created surgically. All arteriovenous communications have a structural and a physiological effect. The structural effect of arterial blood flow on the veins is characteristic; they become dilated, tortuous and thick walled (arterialised). The physiological effect, if the fistula is big enough, is an increase in cardiac output. In extreme circumstances, this can cause left ventricular enlargement and even cardiac failure.

A pulsatile swelling may be present if the lesion is superficial. A thrill is detected on palpation and auscultation reveals a buzzing continuous bruit ('machinery murmur'). Dilated veins may be seen, in which there is rapid blood flow. Pressure on the artery proximal to the fistula reduces the swelling and the thrill and bruit cease.

Duplex scan and/or angiography confirms the lesion, which is noteworthy for the speed with which venous filling occurs.

Management

Treatment is by embolisation. Excisional surgery can be advocated only rarely, perhaps for severe deformity or recurrent haemorrhage; the assistance of a plastic surgeon is wise. It is important to realise that ligation of a 'feeding' artery on its own is of no lasting value and is actually detrimental as it may preclude treatment by embolisation.

ARTERITIS AND VASOSPASTIC CONDITIONS

Thromboangiitis obliterans (Buerger's disease)

This is characterised by occlusive disease of small- and medium-sized arteries (plantar, tibial, radial, etc.), thrombophlebitis of the superficial or deep veins, and Raynaud's syndrome; it occurs in male smokers, usually under the age of 30 years. Often, only one or two of the three manifestations are present. Histologically, there are inflammatory changes in the walls of arteries and veins, leading to thrombosis. Treatment is total abstinence from smoking, which arrests, but does not reverse, the disease. Established arterial occlusions are treated as for atheromatous disease, but amputations may eventually be required.

Other types of arteritis

Arteritis occurs in association with many connective tissue disorders, e.g. rheumatoid arthritis, systemic lupus erythematosus and polyarteritis nodosa. This is usually the province of the specialist physician, but the surgeon may be called on to carry out minor amputations. Sympathectomy has previously been used, but is usually ineffective.

Temporal arteritis is a disease in which localised infiltration with inflammatory and giant cells leads to arterial occlusion, ischaemic headache and tender, palpable, pulseless (thrombosed) arteries in the scalp. Irreversible blindness occurs if the ophthalmic artery becomes occluded. The surgeon may be required to perform a temporal artery biopsy, but this should not delay immediate steroid therapy to arrest and reverse the process before the ophthalmic artery is involved. The length of the biopsy should be at least 1 cm.

Takayasu's disease is an arteritis that obstructs major arteries, particularly the large vessels coming off the aortic arch. It usually pursues a relentless course.

Cystic myxomatous degeneration

This is typified by an accumulation of clear jelly (like a synovial ganglion) in the outer layers of a main artery, especially the popliteal artery. The lesion may narrow the vessel causing claudication. Duplex scan is the investigation of choice. Decompression, by removal of the myxomatous material, is often all that is required, but the 'ganglion' may recur, necessitating excision of part of the artery with interposition vein graft repair.

Raynaud's disease

This idiopathic condition usually occurs in young women and affects the hands more than the feet. There is abnormal sensitivity in the arteriolar response to cold. These vessels constrict and the digits (usually the fingers) turn white and become incapable of fine movements. The capillaries then dilate and fill with slowly flowing deoxygenated blood, resulting in the digits becoming swollen and dusky. As the attack passes off, the arterioles relax, oxygenated blood returns into the dilated capillaries and the digits become red. Thus, the condition is recognised by the characteristic sequence of blanching, dusky cyanosis and red engorgement, often accompanied by pain. Superficial necrosis is very uncommon. This condition must be distinguished from Raynaud's syndrome, which has similar features (see below). Treatment of Raynaud's disease consists of protection from cold and avoidance of pulp and nailbed infection. Calcium antagonists, such as nifedipine, may also have a role to play and electrically heated gloves can be useful in winter. Sympathectomy has been used in the past, but it is either ineffective or its effects are short-lived.

Raynaud's syndrome

Although peripheral vasospasm may be noted in atherosclerosis, thoracic outlet syndrome, carpal tunnel syndrome, etc., the term 'Raynaud's syndrome' is most often used for a peripheral arterial manifestation of a collagen disease, such as systemic lupus erythematosus or rheumatoid arthritis. The clinical features are

as for Raynaud's disease, but they may be much more aggressive. Raynaud's syndrome may also follow the use of vibrating tools. In this context, it is a recognised industrial disease and is known as 'vibration white finger'.

Treatment is directed primarily at the underlying condition, although the conservative measures outlined above are often helpful. The syndrome when secondary to collagen disease leads frequently to necrosis of digits and multiple amputations. Sympathectomy yields disappointing results and is not recommended. Nifedipine, steroids and vasospastic antagonists may all have a role in treatment. Patients with vibration white finger should avoid vibrating tools.

Acrocyanosis

Acrocyanosis may be confused with Raynaud's disease, but it is painless and not episodic. It tends to affect young women and the mottled cyanosis of the fingers and/or toes may be accompanied by paraesthesia and chilblains.

Cervical sympathectomy

Open cervical sympathectomy was previously performed for vasospastic conditions affecting the hands and to treat palmar (sometimes axillary) hyperhidrosis. The operation is now obsolete, having been replaced by endoscopic transthoracic sympathectomy. Furthermore, it has been increasingly recognised that the vasospastic conditions do not respond to this form of treatment, rendering the endoscopic intervention a therapy that is suitable solely for hyperhidrosis.

An endoscope, often a rigid cystoscope, is used. The ipsilateral lung may be deflated by the anaesthetist and a cannula inserted into the chest wall to permit easy access for the scope. The sympathetic chain is visualised and a coagulating electrode used to ablate the ganglia below the stellate. The scope and cannula are then removed, the lung inflated and the small chest wound closed.

Lumbar sympathectomy

Lumbar sympathectomy has been used to treat chronic lower limb ischaemia in the past. Lumbar sympathectomy by open operation has, however, been obsolete for several years and even chemical sympathectomy, its minimally invasive equivalent, can now be regarded as outdated. Chemical sympathectomy requires the injection of small quantities of a sclerosant into the lumbar sympathetic chain under radiographic control.

LEARNING OBJECTIVES

To understand:

- Venous anatomy and the physiology of venous return
- The pathophysiology of venous disease
- The clinical significance and management of varicose veins
- Deep venous thrombosis
- Venous insufficiency and venous ulceration

THE ANATOMY OF THE VENOUS SYSTEM OF THE LIMBS

Arterial blood flows through the main axial arteries of the upper and lower limbs before returning via the deep and superficial veins. All of the veins of the upper and lower limbs contain valves, which ensure that blood flows towards the heart.

The superficial venous trunks in the leg are the greater (long) and lesser (short or small) saphenous veins (Figure 57.1a and b), which lie above the muscle fascia of the limb. The cephalic and basilic veins are the superficial venous trunks of the arm (Figure 57.1c and d). Although the long saphenous vein is classically said to join the femoral vein at the saphenofemoral junction, a fixed point in the groin 2.5 cm below and lateral to the pubic tubercle, it is usually encountered somewhat higher. The lesser saphenous vein joins the popliteal vein at the saphenopopliteal junction at a variable site in the popliteal fossa but generally proximally to the knee joint crease. Blood passing up the superficial veins enters the deep veins at the saphenopopliteal and saphenofemoral junctions.

In the calf and thigh there are a number of valved perforating (communicating) veins that join the superficial to the deep veins at inconstant sites and which allow blood to flow from the superficial to the deep venous system. The most important of these are the direct perforating veins of the medial and lateral calf and the communicating veins around the knee and in the mid-thigh.

The deep veins of the lower limb include three pairs of venae comitantes, which accompany the three crural arteries (anterior and posterior tibial and peroneal arteries). These six veins intercommunicate and join in the popliteal fossa to form the popliteal vein, which also receives the soleal and gastrocnemius veins.

The popliteal vein passes up through the adductor hiatus to enter the subsartorial canal as the superficial femoral vein, which receives the deep (profunda) femoral vein (or veins) in the femoral triangle to become the common femoral vein, which then changes its name to the external iliac vein as it passes behind the inguinal ligament. The internal iliac vein joins with the

external iliac vein in the pelvis to form the common iliac vein. The left common iliac vein passes behind the right common iliac artery to join the right common iliac vein on the right side of the abdominal aorta to form the inferior vena cava.

VENOUS PATHOPHYSIOLOGY

Blood enters the lower limb through the femoral arteries before passing through arterioles into the capillaries, which have a pressure of about 32 mmHg at their arterial ends. This pressure is reduced along the course of the capillaries and is approximately 12 mmHg at the venular end of the capillary. The pressure continues to fall in the main veins and is as low as -5 mmHg at the upper end of the vena cava where it enters the right atrium.

The venous pressure in a foot vein on standing is equivalent to the height of a column of blood extending from the heart to the foot, e.g. approximately 100 mmHg (Figure 57.2). To enable blood to be returned against gravity in the standing position, an auxiliary pump is required in the lower limb. This is the calf muscle pump, which is augmented to a lesser extent by the thigh and foot pumps. The deep veins of the calf are capacious and are joined by blind-ending sacks called the soleal sinusoids, which force blood into the popliteal and crural veins during calf muscle pump contraction, e.g. walking. The foot pump also ejects blood from the plantar veins during walking. As the calf muscles contract, the veins are compressed and the valves only allow blood to pass in the direction of the heart. The pressure within the calf compartment rises to 200–300 mmHg during muscle contraction. During muscle relaxation the pressure falls and blood from the superficial veins enters the deep veins through the saphenous junctions and the perforating veins. Each time this occurs the pressure falls in the superficial venous compartment until a threshold is reached, when the venous inflow keeps pace with ejection from the deep veins. This is normally around 30 mmHg, a fall of approximately two-thirds of the resting venous pressure. The net reduction in the pressure of the superficial system is dependent on the presence of patent deep veins, perforating veins and superficial veins, which must contain competent valves. Ambulatory venous hypertension is a consequence of

valve failure (reflux) or obstruction in the venous system and may eventually lead to lipodermatosclerosis and ulceration.

The pathophysiology of varicose vein development is probably related to changes in the vein wall (dysfunctional smooth muscle cell proliferation, collagen deposition, decreased elastin content and increased matrix metalloproteinases) leading to venous dilatation and secondary valvular incompetence rather than to a primary valvular defect, which occurs in a small group of patients who have total lack of venous valves. Secondary varicose veins may develop in patients with post-thrombotic limbs and in patients with congenital abnormalities such as the Klippel–Trenaunay syndrome or multiple arteriovenous fistulae.

Simplistically, venous disease can be divided into superficial venous incompetence and deep venous incompetence or a combination of these along with their clinical presentations.

VARICOSE VEINS

Varicose veins are defined as dilated, usually tortuous, subcutaneous veins ≥ 3 mm in diameter measured in the upright position with demonstrable reflux.

Epidemiology

The adult prevalence of visible varicose veins is 25–30 per cent in women and 15 per cent in men. Factors affecting prevalence include:

- **gender:** the vast majority of studies report a higher prevalence in women than men, the Edinburgh Vein Study being the main exception;

Klippel and Trenaunay described the condition in 1900. Seven years later, Frederick Parkes-Weber, 1863–1962, an English physician, also described the condition, hence also called Klippel–Trenaunay–Weber syndrome.

Maurice Klippel, 1858–1942, neurologist, La Salpêtrière, Paris, France.
Paul Trenaunay, born 1875, a French neurologist.

- **age:** the prevalence of varicose veins increases with age. In the Edinburgh Vein Study, the prevalence of trunk varicosities in the age groups 18–24 years, 25–34 years, 35–44 years, 45–57 years and 55–64 years was 11.5, 14.6, 28.8, 41.9 and 55.7 per cent, respectively;
- **ethnicity:** does seem to influence the prevalence of varicose veins;
- **body mass and height:** increasing body mass index and height may be associated with a higher prevalence of varicose veins;
- **pregnancy:** appears to increase the risk of varicose veins;
- **family history:** evidence supports familial susceptibility to varicose veins;
- **occupation and lifestyle factors:** there is inconclusive evidence regarding increased prevalence of varicose veins in smokers, patients who suffer constipation and occupations which involve prolonged standing.

Classification

The CEAP (clinical – etiology – anatomy – pathophysiology) classification for chronic venous disorders is widely utilised.

Clinical classification

- C0: no signs of venous disease
- C1: telangectasia or reticular veins
- C2: varicose veins
- C3: oedema
- C4a: pigmentation or eczema
- C4b: lipodermatosclerosis or atrophie blanche
- C5: healed venous ulcer
- C6: active venous ulcer

Each clinical class is further characterised by a subscript depending upon whether the patient is symptomatic (S) or asymptomatic (A) e.g. C2S.

Etiologic classification

- Ec: congenital
- Ep: primary
- Es: secondary (post-thrombotic)
- En: no venous cause identified

Anatomical classification

- As: superficial veins
- Ap: perforator veins
- Ad: deep veins
- An: no venous location identified

Pathophysiological classification

- Pr: reflux
- Po: obstruction
- Pr,o: reflux and obstruction
- Pn: no venous pathophysiology identifiable

Clinical features

Symptoms

Varicose veins frequently cause symptoms, the most common being aching or heaviness, which typically increases throughout the day or with prolonged standing and is relieved by elevation or compression hosiery. Other less common symptoms include ankle swelling and itching while complications (bleeding, superficial thrombophlebitis, eczema,

Figure 57.3 Varicose veins. (a) Left leg varicose veins in the distribution of an incompetent long saphenous vein (marked for intervention). (b) Right leg varicose veins in the distribution of the short saphenous system with a recent episode of phlebitis. (c) Varicose veins in distribution of an isolated incompetent proximal anterolateral tributary of the long saphenous system with associated gaiter area skin changes.

superficial system is defective; medial thigh and calf varicosities suggest long saphenous incompetence (Figure 57.3a), posterolateral calf varicosities are suggestive of short saphenous incompetence (Figure 57.3b), whereas anterolateral thigh and calf varicosities may indicate isolated incompetence of the proximal anterolateral long saphenous tributary (Figure 57.3c). Percussion over the varices may elicit an impulse tap by the fingers placed over the dilated trunk.

Other signs commonly found include:

- Telangiectasia, which are essentially a confluence of dilated intradermal venules <1 mm in diameter. These may be mild or severe (Figure 57.4). Synonyms include spider veins, thread veins and hyphen webs.
- Reticular veins are dilated, subdermal veins, 1–3 mm in diameter. The presence of telangiectasia and reticular veins are of dubious significance, are not necessarily associated with major varicose veins and are purely a cosmetic problem.
- In saphena varix (Figure 57.5), there is a large groin varicosity which presents as a (usually painless) lump, emergent when standing and disappearing when recumbent. Gentle palpation over the varix during coughing may elicit a thrill.
- Atrophie blanche (Figure 57.6) is localised white atrophic skin frequently surrounded by dilated capillaries and hyperpigmentation, usually seen around the ankle.
- Corona phlebectasia are fan-shaped patterns of small intradermal veins on the medial or lateral aspects of the ankle or foot. Synonyms include malleolar or ankle flares.

lipodermatosclerosis and ulceration) represent important indications for investigation and intervention. The Edinburgh Vein Study failed to show any evidence that the extent of valvular incompetence was related to the severity of symptoms.

Signs

The presence of tortuous dilated subcutaneous veins are usually clinically obvious. These are confined to the long and lesser saphenous systems in approximately 60 and 20 per cent of cases, respectively. The distribution of varicosities may indicate which

Figure 57.4 Severe telangiectasia.

Figure 57.5 A saphena varix.

- Pigmentation (Figure 57.7) is usually a brown discolouration (because of haemosiderin deposition) of the skin, most frequently affecting the gaiter area, and may be associated with phlebitis and ulceration.
- Eczema (Figure 57.8a); this is an erythematous dermatitis which may progress to blistering, weeping or scaling eruption of the skin, not to be confused with contact dermatitis (Figure 57.8b).
- Dependent pitting oedema as a result of increase in volume of fluid in skin and subcutaneous tissue characteristically increases throughout the day, and is relieved by elevation and compression hosiery/bandaging. The oedema is usually

Figure 57.6 Atrophie blanche.

Figure 57.7 Pigmentation: brown discoloration of the skin, most frequently affecting the gaiter area associated with chronic venous insufficiency.

confined to the ankle area but may extend to the foot and rest of the leg.

- Lipodermatosclerosis (Figure 57.9) is a localised chronic inflammation and fibrosis of the skin and subcutaneous tissues of the leg, a sign of severe chronic venous disease.
- Ulceration (Figure 57.10) is a full thickness epidermal defect, most frequently affecting the gaiter area.

Investigation

Tourniquet tests have now largely been abandoned. There is good evidence to support the policy of duplex ultrasound scanning for all patients with varicose veins prior to any intervention. This policy facilitates a more accurate surgical approach, reduces the incidence of varicose vein recurrence, and allows assessment regarding suitability for endovenous intervention. Clinical acumen combined with continuous wave hand-held Doppler examination will miss up to 30 per cent of important connections between superficial and deep veins and information

Figure 57.8 Excema. (a) Erythematous dermatitis; (b) contact dermatitis.

Figure 57.9 Lipodermatosclerosis of the calf skin.

Figure 57.10 A venous ulcer.

on affected veins when compared to duplex scanning; thus, it should only be utilised as the basis for intervention when duplex scanning is not available.

Hand-held continuous wave Doppler emits a sound when blood flows past the transmitting and receiving crystals. A uni-phasic signal indicates flow in one direction. Forward and reverse flow produces a biphasic signal which is indicative of blood refluxing through incompetent valves. A biphasic signal following a calf squeeze performed with the Doppler probe over the saphenofemoral junction suggests the presence of junctional incompetence. A biphasic signal over the saphenopopliteal junction or lesser saphenous vein is not an accurate method of establishing incompetence of the lesser saphenous vein as its termination is variable and it is difficult to separate lesser saphenous incompetence from popliteal valvular incompetence. In all cases of biphasic lesser saphenous signal a duplex scan should be performed.

Duplex ultrasound imaging

Duplex ultrasound imaging has become the main stay of investigation for varicose veins. A high-frequency linear array transducer of 7.5–13 MHz is appropriate for the majority of lower limbs in order to obtain good quality images. The B mode settings (depth, focal zone, overall gain and dynamic gain) should be optimised to ensure the area of interest is in the centre and occupies the majority of the image, and that the lumen of the vein appears as a dark void in the subcutaneous and deep tissues. The pulsed wave spectral or colour Doppler settings should be optimised for the low flow velocities encountered within veins. It is conventional to use blue to represent antegrade venous flow towards the heart and red for the reverse. Visible venous flow can be augmented by a calf squeeze.

The aim of the duplex scan in patients with varicose veins is to establish:

- which saphenous junctions are incompetent and their locations;
- the extent of reflux in the saphenous veins and their diameters;
- the number, location and diameter of incompetent perforating veins;

- other relevant veins that demonstrate reflux;
- the source of all superficial varices if not from the veins already described;
- the competence and evidence of previous venous thrombosis in the deep venous system.

In order to standardise measurements of venous diameter and reflux, it is recommended that examination of the superficial veins is performed with the patient standing. Venous reflux is defined as retrograde flow in the reverse direction to physiological flow lasting for more than 0.5 seconds. Reflux may be elicited by release of a calf or foot squeeze for proximal or calf varicosities respectively, manual compression over varicosity clusters, pneumatic calf cuff deflation, active foot dorsiflexion and relaxation or the Valsalva manoeuvre.

The patient should stand facing towards the examiner with the leg rotated outwards, heel on the ground and weight on the opposite limb (Figure 57.11). The scan should begin in the groin, using a transverse view to identify the long saphenous vein and common femoral vein lying medial to the common femoral artery (the 'Micky Mouse' sign – Figure 57.12). Saphenofemoral junction (SFJ) competence is assessed in the transverse view and potential destinations for reflux including the greater or long saphenous vein (LSV), the accessory anterior saphenous vein and other major thigh tributaries superficial to the saphenous fascia are noted. The full length of the LSV within its fascial compartment, known as the 'saphenous eye', should be examined (Figure 57.13), and its diameter measured just below the SFJ, mid-thigh, above and below the knee joint, mid-calf and ankle. The groin is next examined for reflux in the longitudinal plane in the common femoral vein, superficial femoral vein and SFJ using spectral and/or colour Doppler (Figure 57.14). The presence and competence of thigh and calf perforators should be noted. For examination of the lesser or short saphenous vein

Figure 57.11 Patient position for venous duplex examination of the long saphenous system.

Figure 57.12 'Micky Mouse' transverse B mode image of right common femoral vein (R CFV) and right common femoral artery (R CFA) and greater saphenous vein (GSV) at the saphenofemoral junction (SFJ).

Figure 57.14 Duplex scan of the saphenofemoral junction showing antegrade and retrograde flow.

(SSV) and posterior thigh extension of the SSV (Giacomini vein), the patient is positioned facing away, knee slightly flexed, heel on the ground and the weight taken on the opposite leg. If the saphenopopliteal junction (SPJ) is incompetent, the level of the SPJ in relation to the knee crease and whether the SSV joins the popliteal vein posteriorly, medially or laterally is noted. In the transverse view, the SSV vein is followed distally, checking its competence and diameter in the proximal, mid and distal

Figure 57.15 Varicogram.

calf. Finally, the patency and competence of the popliteal vein is assessed.

Very occasionally, investigations other than duplex are required, usually when duplex demonstrates reflux in superficial varicosities but fails to identify any site of junctional incompetence. Varicography involves injection of contrast directly into superficial varices which allows detailed mapping of the varices to their termination. This can be useful in patients with recurrent varicose veins or with complex anatomy (Figure 57.15). Descending intravenous venography where contrast is injected via the deep veins or magnetic resonance venography is useful when lower limb varicosities appear to arise from pelvic vein incompetence.

Management

Patients who have asymptomatic varicose veins can simply be reassured. Indications for referral to a vascular surgeon include C2 disease associated with bleeding, superficial thrombophlebitis or symptoms which are impairing quality of life, or C3–6 disease.

Compression hosiery

Compression hosiery relies on graduated external pressure to improve deep venous return. Compression hosiery can be knee length or thigh length; there is no evidence which length of stocking is more effective and hence below-knee stockings are usually prescribed as they are easier to don and have much better patient acceptance. Compression hosiery is classified according to the pressure exerted, and the British classification class 1 stockings exert pressure of 14–17 mmHg, class 2 exert 18–24 mmHg and class 3 exert 25–35 mmHg. Compression hosiery significantly improves varicose vein symptoms but is not popular with patients with compliance rates and long-term tolerance being universally poor. There is no evidence to suggest that compression hosiery prevents the occurrence or progression of varicose veins. Finally, the incorrect application of compression hosiery can have serious consequences (pressure necrosis, tourniquet effects); thus assessment, prescription and application of compression hosiery should be limited to those with the appropriate skills and training.

Ultrasound-guided foam sclerotherapy

Ultrasound-guided foam sclerotherapy involves the injection of detergent directly into the superficial veins. The most commonly

used (and only sclerosant recognised for treatment in the UK) is sodium tetradecyl sulphate although others are available on a named patient basis. The detergent destroys the lipid membranes of endothelial cells causing them to shed, leading to thrombosis, fibrosis and obliteration (sclerosis). The procedure commences with the patient standing, and the sites of venous cannulation are selected and marked using ultrasound. Then, with the patient supine, the major venous trunks and superficial varicosities to be treated are all cannulated using ultrasound guidance (Figure 57.16). This is performed before injection as the injection quickly spreads through the superficial varicosities making further cannulation difficult. Once all injection sites are cannulated the injection can be prepared. The most widely used method is that of Tessari, which utilises two syringes connected using a three-way tap. A 1:3 or 1:4 ratio mixture of sclerosant and air is drawn into one syringe, and is then oscillated vigorously between the two syringes about 10 or 20 times (Figure 57.17). The foam produced in this way is stable for about 2 minutes so it

Figure 57.16 Foam sclerotherapy; cannulation of varicosities for ultrasound-guided foam sclerotherapy.

Figure 57.17 Foam sclerotherapy; Tessari method of foam sclerosant preparation.

Carlo Giacomini, 1840–1898, anatomist, Turin, Italy, on his death left his skeleton to the Anatomical Museum in Turin.

Lorenzo Tessari, born 1949, an Italian physician.

William George Fegan, 1921–2007, Emeritus Professor of Surgery, Trinity College, Dublin, Ireland.

should be injected as soon as it has been made. The leg is then elevated to empty the veins of blood, and injection of foam commences first with superficial varicosities and ends with injection of the LSV or SSV. Only 1 or 2 mL of foam should be injected at a time and the distribution of the foam should be monitored and massaged with the ultrasound probe. When the foam is visualised at the site of junctional incompetence no further foam should be injected. The maximum volume of foam which should be injected at a single session should not exceed 10–12 mL as the incidence of complications are directly related to the volume of foam injected. Compression bandaging or hosiery is then applied and left *in situ* for 7–10 days. Sclerotherapy improves varicose vein-related symptoms, but recurrence rates and the need for reintervention are relatively high. Foam is superior to liquid sclerotherapy, as popularised by George Fegan, in achieving LSV obliteration at two years. Some complications (phlebitis, pigmentation, headache, visual disturbance, chest tightness, cough) are relatively common. There is no robust randomised controlled trial data to influence choice of sclerosant, local pressure dressings, or duration of postsclerotherapy compression. Short-term bandaging is better tolerated than more prolonged bandaging.

Endovenous laser ablation

Endovenous laser ablation (EVLA) as a treatment for varicose veins was first described in 2001, and involves the insertion of a laser fibre into the lumen of an incompetent truncal vein, with subsequent thermal ablation of the vein. The vast majority of patients with primary and recurrent varicose veins are suitable for EVLA, with success reported in treating the long, short and anterior saphenous veins, perforators and varicosities themselves. The factors which may preclude EVLA pertain to either the patient (unsuitable for local anaesthesia, e.g. needle phobia) or the vein (excess tortuosity, thrombophlebitis).

The procedure begins with ultrasound-guided marking of the truncal vein to be treated and the site of proposed cannulation. The varicosities are also marked at this stage if concomitant treatment (phlebectomy, foam sclerotherapy) is to be undertaken. The patient is then positioned on the procedure couch in the reverse Trendelenburg position. For the LSV, the patient is supine with the hip of the leg to be treated externally rotated and slightly flexed. A pillow under the contralateral hip/lower back may improve patient comfort. For the SSV, the patient is positioned in the prone position. The vein is then cannulated percutaneously under ultrasound guidance, at the lowest point of reflux. A wire is then passed through the needle into the superficial vein through the site of junctional incompetence into the deep vein. The catheter is then passed over the wire and positioned within 1 cm of the site of junctional incompetence. Accurate positioning of the catheter tip (and thus the laser fibre tip) with ultrasound is crucial (Figure 57.18). Following the administration of perivenous tumescent anaesthesia (Figure 57.19a and b), the laser fibre is introduced into the catheter (Figure 57.20), passed to the catheter tip and laser energy is used to ablate the vein.

The tumescent anaesthesia during EVLA provides analgesia and compresses the vein, increasing the contact area between the vein wall and laser fibre. It also protects adjacent structures (skin, nerves) by causing hydrodissection and acting as a heat sink. Dilute lidocaine with adrenaline and bicarbonate warmed to body temperature is recommended. It is important not to exceed the recommended dose.

As EVLA treats only junctional and truncal incompetence, debate exists regarding the management of varicosities. These can be managed concomitantly or sequentially by either phlebectomy or sclerotherapy. Concomitant phlebectomies (Figure 57.21) result in a more rapid improvement in disease-specific quality of life, and allow the vast majority of patients to complete treatment in a single visit. Compression and analgesia are usually recommended in the early postoperative period.

Radiofrequency ablation

Radiofrequency ablation (RFA) is a minimally invasive endovascular therapy that uses a bipolar catheter to generate thermal energy to ablate the vein. Preoperative planning and consent, patient positioning, tumescent anaesthesia administration and postoperative management are identical to EVLA. The main differences include vein cannulation and method of ablation. The vein to be treated is cannulated with a 7FG sheath using ultrasound guidance and the catheter is introduced through the sheath and the catheter tip positioned not within 2 cm of the incompetent junction (Figure 57.22). The catheter generates temperatures of 85–120°C, typically using a power of 2–4 W,

Figure 57.21 Phlebectomies performed under tumescent anaesthesia following endovenous thermal ablation.

Figure 57.22 Radiofrequency ablation – introducing catheter through sheath.

to ablate the vein. The thermal energy can be applied continuously using a continuous pull-back technique or sequentially over 7-cm segments depending on the RFA catheter of choice. Recent trials comparing RFA and EVLA suggest the former may be associated with less pain and bruising.

The incidence of complications following endovenous interventions are low but include thromboembolic complications (<1 per cent), phlebitis (<5 per cent – reduced with non-steroidal anti-inflammatory drugs (NSAIDs) and skin burns (<2 per cent – the majority occurring in patients not given tumescence).

Surgery

The principles of the operation are to ligate the point of junctional incompetence and to remove the refluxing trunk and dilated tributaries. Preoperatively, a careful consent is taken, explaining the risks of infection, minor nerve injury and recurrence, and the varicose veins must be tramlined using an indelible marker pen to enable accurate identification varicosities during surgery. The operation is usually performed under general anaesthesia but locoregional anaesthesia is possible.

Saphenofemoral ligation and long saphenous stripping

An oblique groin incision is made at the level of and lateral to the pubic tubercle. The long saphenous vein is identified and dissected to the SFJ, which should be clearly established before the vein is divided to avoid disasters (Figure 57.23). Six LSV tributaries are normally encountered close to the SFJ, the superficial inferior epigastric vein and superficial circumflex iliac vein laterally, the deep and superficial external pudendal veins medially, and usually more distally the anterolateral and posteromedial thigh veins, which should be ligated and divided. A flush SFJ ligation is then performed and the LSV retrogradely

Figure 57.23 Saphenofemoral junction ligation and stripping.

stripped to the knee. The tributary varicosities should then be avulsed through small incision along Langer's lines, using small hooks or mosquito forceps. Closure of the cribriform fascia, with sutures or synthetic patches, over the ligated SFJ, has not been demonstrated to reduce groin recurrence. Stripping the LSV reduces the rate of reintervention for recurrent varicose veins, but it should only be stripped to knee level, as stripping to the ankle does not improve symptomatic relief, but significantly increases the risk of saphenous nerve injury.

Saphenopopliteal junction ligation and lesser saphenous stripping

Preoperative duplex to mark the position of the SPJ is highly recommended (Figure 57.24). The patient is positioned in the prone position, a transverse incision is made over the premarked

Figure 57.24 Preoperative marking of saphenopopliteal junction and short saphenous vein mapped using duplex scanning.

SPJ, the fascia is divided and the SSV is exposed. The SPJ can then be formally dissected with a flush ligation or the SSV can be gently retracted and ligated as proximally as possible. No good evidence exists to favour one technique over the other, but proponents of the flush ligation would argue that it avoids leaving a stump of SSV, a common source of recurrence, while proponents of the simple SSV ligation technique argue it reduces the incidence of the most common serious complications, nerve injury and popliteal vein injury. The SSV can then either be stripped or the proximal section of the vein can be resected. Those who strip argue it reduces the incidence of recurrence while opponents feel it increases the incidence of sural nerve injury. There are no randomised trials comparing these techniques.

Perforator ligation

The majority of studies assessing the role of perforator ligation have been in patients with venous ulcers analysing the effects on ulcer healing, and even in this situation randomised controlled data are lacking. The role of perforator ligation in patients with uncomplicated varicose veins is even less clear. The traditional procedure described by Linton and Cockett has fallen out of favour due to the associated high incidence of wound complications. In uncomplicated varicose veins, perforators may be ligated through a small, duplex-guided incision, while in patients with skin changes, subfascial endoscopic perforator ligation may be preferred, although the benefits are unproven.

Phlebectomies

These may be performed following treatment of junctional incompetence and axial vein reflux or as sole treatment under

local anaesthetic in patients with isolated tributary incompetence. Phlebectomies are usually performed through small stab incisions using small mosquito forceps and/or phlebectomy hooks which have been demonstrated to be superior in terms of bruising, pain and generic quality of life than transilluminated-powered phlebectomy (TIPP).

Complications of standard varicose vein surgery

Complications (minor and major) are reported in up to 20 per cent of patients who undergo traditional varicose vein surgery. Wound infections, the most common complication, are reduced by prophylactic antibiotics. Nerve injury is the most common serious complication. The incidence of saphenous nerve neuralgia is up to 7 per cent following LSV stripping to the knee (the incidence is higher with stripping to the ankle). The incidence of sural nerve neuropraxia and common peroneal nerve injury may be as high as 20 and 4 per cent, respectively, following SSV surgery. The incidence of venous thromboembolic complications is approximately 0.5 per cent following varicose vein surgery, however patient risk factors must be individually assessed and appropriate prophylaxis administered according to guidelines.

Comparison of interventions

Endovenous and traditional surgery for varicose veins appear equally beneficial in improving generic and disease-specific quality of life in the short to medium term. However in the early postoperative period, traditional surgery is associated with higher pain scores and analgesic requirement, and more severe disability in terms of physical, social and psychological quality of life although the clinical significance of this is unclear. Thus endovenous interventions, by minimising the immediate postoperative quality of life impairment, result in a more rapid return to work and normal activities. Adequately powered, long-term comparisons of recurrence rates following surgery and endovenous interventions are awaited.

Recurrent varicose veins

Approximately 10–20 per cent of patients who present to hospital with varicose veins have had previous intervention. Prospective data on long-term results following intervention for recurrent varicose veins are sparse and the criteria for defining recurrence are variable.

Significant clinical recurrence five to ten years following varicose vein surgery occurs in 10–35 per cent of patients, but minor/duplex detected recurrence is much more common being in the order of 70 per cent. Causes of recurrence are controversial but include: neo-revascularisation; reflux in residual axial vein; inadequate initial surgery; and new junctional reflux. Recurrence is more common following short than long saphenous vein surgery and in patients with high BMI (body mass index), while stripping of the incompetent axial vein reduces recurrence rates. Limited data suggest recurrence rates following endovenous thermal ablation may be lower and of different aetiology (axial vein recanalisation) than following surgery. Recurrent varicose veins often have an atypical distribution and duplex assessment is mandatory (Figures 57.25 and 57.26). Surgery for recurrent varicose veins is associated with a high (40 per cent) complication rate, the most common being lymph leak and wound infection, thus endovenous interventions would seem to offer an attractive alternative, where feasible.

Figure 57.25 Recurrent anterior abdominal wall varicose veins following saphenofemoral junction ligation complicated by iliac deep venous thrombosis.

Figure 57.26 Recurrent varicose veins secondary to an incompetent thigh perforator.

Pelvic congestion syndrome

Pelvic congestion syndrome (PCS) is among the differential diagnoses to be considered in female patients presenting with chronic pelvic pain. PCS sufferers are typically premenopausal, multiparous women aged 20–45 years, who present with severe dull aching pelvic pain thought to be the direct result of ovarian and pelvic varicosities. The pain is usually non-cyclical, and may be precipitated by prolonged standing. Other symptoms include dysmenorrhoea, menorrhagia, rectal discomfort or urinary frequency. Signs may include tenderness over the uterus/ovaries, vulval varicosities and haemorrhoids. There may be vulval and

Figure 57.27 (a–c) Left ovarian vein incompetence supplying pelvic and pudendal varicosities (diagnostic venogram and therapeutic embolisation).

atypically distributed thigh varicosities. The road to a diagnosis of PCS is often a long and laborious one, usually only made following extensive investigations to exclude other more common causes of pelvic pain. Abdominal, pelvic and transvaginal duplex examinations allow dynamic visualisation of pelvic blood flow and should be the initial investigations of choice, as they are rapid, readily accessible outpatient procedures which are also valuable in excluding other pathologies. However, the sensitivity for PCS of magnetic resonance venography or diagnostic venography is superior.

Medical treatments for PCS include psychotherapy, progestins, danazol, gonadotrophin receptor agonists (GnRH) with hormone replacement therapy, and NSAIDs. Historical open surgical procedures (extraperitoneal resection of ovarian veins) have now largely been superseded by percutaneous pelvic vein embolisation (Figure 57.27c), reducing peri- and postprocedural morbidity while maintaining high success rates.

VENOUS THROMBOSIS

Venous thrombosis is the formation of a semi-solid coagulum within the venous system and may occur in the superficial system (usually described as superficial thrombophlebitis) or the deep system (deep venous thrombosis or DVT). Venous thrombosis of the deep veins of the leg may be complicated by the immediate risk of pulmonary embolus and sudden death. Subsequently, patients are at risk of developing a post-thrombotic limb (Figure 57.28) and venous ulceration. While DVT may occur in the upper limb, it is the leg that gives rise to the vast majority of the morbidity and subsequent complications of this condition.

Aetiology

The three factors described by Virchow over a century ago are still relevant in the development of venous thrombosis. These are:

- changes in the vessel wall (endothelial damage);
- stasis, which is diminished blood flow through the veins;
- coagulability of blood (thrombophilia).

There are many predisposing causes for venous thrombosis. These are listed in Table 57.1. The most important factor is a hospital admission for the treatment of a medical or surgical condition. Injury, especially fractures of the lower limb and pelvis, pregnancy and the oral contraceptive pill are other well-recognised predisposing factors. Endothelial damage is now known to be critically important. The interaction of the endothelium with inflammatory cells, or previous deep vein damage, renders the endothelial surface hypercoagulable and less fibrinolytic.

Stasis is a predisposing factor seen in many of the conditions described in Table 57.1, especially in the postoperative period, in patients with heart failure and in those with arterial ischaemia.

Table 57.1 Risk factors for venous thromboembolism.

Patient factors	Age
	Obesity
	Varicose veins
	Immobility
	Pregnancy
	Puerperium
	High-dose oestrogen therapy
	Previous deep vein thrombosis or pulmonary embolism
	Thrombophilia (see Table 57.2)
Disease or surgical procedure	Trauma or surgery, especially of pelvis, hip and lower limb
	Malignancy, especially pelvic, and abdominal metastatic
	Heart failure
	Recent myocardial infarction
	Paralysis of lower limb(s) infection
	Inflammatory bowel disease
	Nephrotic syndrome
	Polycythaemia
	Paraproteinaemia
	Paroxysmal nocturnal haemoglobinuria antibody or lupus anticoagulant
	Behçet's disease
	Homocystinaemia

A number of conditions are associated with increased coagulability of the blood (thrombophilia) (Table 57.2). Deficiencies of antithrombin, activated protein C and protein S have all been shown to predispose to venous thrombosis in young patients. Activated protein C deficiency is associated with inheritance of the factor V Leiden gene and may account for the higher incidence of venous thrombosis in Caucasian populations (being present in 6–7 per cent). It results in a small increase in the risk of venous thrombosis, although it may act in concert with some of the other predisposing factors. A thrombophilic cause should be sought in any patient presenting with an episode of venous thrombosis who gives a family history of deep vein thrombosis or in whom there is no other predisposing factor.

Although the development of deep vein thrombosis is probably multifactorial, immobility (and hence stasis) remains one of the most important factors. Deep vein thrombosis is recognised as a complication of long-haul flights and other forms of travel.

Table 57.2 Abnormalities of thrombosis and fibrinolysis (thrombophilia) that lead to an increased risk of venous thrombosis.

Congenital	Deficiency of antithrombin III, protein C or protein S

Acquired	Antiphospholipid antibody or lupus anticoagulant

Figure 57.28 Post-thrombotic leg.

Pathology

A thrombus often develops in the soleal veins of the calf, initially as a platelet aggregate. Subsequently, fibrin and red cells form a mesh until the lumen of the vein wall occludes. The coralline thrombus then progresses as a propagated loose red fibrin clot containing many red cells (Figure 57.29). This is likely to extend up to the next large venous branch and it is possible for the clot to break off and embolise to the lung as a pulmonary embolism. In this situation the embolus arising from the lower leg veins becomes detached, passes through the large veins of the limb and vena cava, through the right heart and lodges in the pulmonary arteries. This may totally occlude perfusion to all or part of one or both lungs (pulmonary embolism). Acute right heart obstruction may lead to sudden collapse and death. Lung infarction is rare as the lung has a dual blood supply (bronchial and pulmonary arteries). Moderate-sized emboli can cause pyramidal-shaped infarcts.

Figure 57.29 An organised thrombus. C, clot; T, thrombus.

Diagnosis

The most common presentation of a deep vein thrombosis is pain and swelling, especially in the calf – usually in one lower limb; however, bilateral deep vein thromboses are common, occurring in up to 30 per cent. When the swelling is bilateral, deep vein thromboses must be differentiated from other causes of systemic oedema, such as hypoproteinaemia, renal failure and heart failure. Some patients have no symptoms of thrombosis and may first present with signs of a pulmonary embolism, e.g. pleuritic chest pain, haemoptysis and shortness of breath. Patients may also develop shortness of breath from chronic pulmonary hypertension. Sometimes the leg appears cellulitic and, very occasionally, it may be white or cyanosed: phlegmasia alba dolens and phlegmasia cerulia dolens (Figure 57.30). Patients who present with venous gangrene (Figure 57.31) often have an underlying neoplasm.

Clinical examination for DVT is unreliable. Physical signs may also be absent. Mild pitting oedema of the ankle, dilated surface veins, a stiff calf and tenderness over the course of the deep veins should be sought. Leg pain occurs in about 50 per cent of patients with DVT but is non-specific. Homans' sign – resistance (not pain) of the calf muscles to forcible dorsiflexion

Figure 54.30 Phlegmasia cerulia dolens.

Figure 57.31 A foot with venous gangrene. The gangrene is symmetrical involving all of the toes. There is no clear-cut edge and there is marked oedema of the foot.

– is not specific and should not be elicited. Tenderness occurs in 75 per cent of patients but is also found in 50 per cent of patients without objectively confirmed DVT. The pain and tenderness associated with DVT does not usually correlate with the size, location or extent of the thrombus. Clinical signs and symptoms of pulmonary embolism occur in about 10 per cent of patients with confirmed DVT.

A low-grade pyrexia may be present, especially in a patient who is having repeated pulmonary emboli. Patients may have signs of cyanosis, dyspnoea, raised neck veins, a fixed split second heart sound and a pleural rub if they are having pulmonary emboli causing right heart strain, although these signs may be subtle or lacking.

Investigation

The diagnosis of deep vein thrombosis and pulmonary embolism should be established by special investigations as the symptoms and signs are non-specific and may be entirely lacking. In addition, treatment with anticoagulation is not without risk and the diagnosis must be made with reasonable certainty.

Patients who present to an Accident and Emergency department with an idiopathic thrombosis usually have a d-dimer measurement where the modified Wells score is long than 4 or there is clinical suspicion (Table 57.3). If this is greater than the normal range there is no indication for further investigation but, if raised, a duplex compression ultrasound examination of the deep veins should be performed. The deep veins of the lower limb are located and compressed. Filling defects in flow and a lack of compressibility indicate the presence of a thrombosis (Figure 57.32). This is accurate and reliable for femoral and popliteal clots but less certain in tibial vein clots.

Ascending venography, which shows a thrombus as a filling defect, is now rarely required unless other measures are being considered (Figure 57.33). Magnetic resonance imaging

Figure 57.32 A longitudinal (a) and transverse (b) section of a duplex scan of a vein containing a thrombus.

Table 57.3 Modified Wells criteria for predicting pulmonary embolism.

Variable	Points
Clinical signs and symptoms of DVT (minimum of leg swelling and pain on palpation of deep veins)	3.0
Alternative diagnosis less likely than PE	3.0
Heart rate >100	1.5
Immobilisation >3 days or surgery within past 4 weeks	1.5
Previous DVT or PE	1.5
Haemoptysis	1.0
Malignancy (treatment or palliation within past 6 months)	1.0

DVT, deep venous thrombosis; PE, pulmonary embolism.
A score of <4 means PE is unlikely; >4 is suggestive of PE.

Figure 57.33 An ascending venogram of a deep vein thrombosis seen as filling defects (arrows) with contrast passing around the thrombus.

(MRI) uses a magnet to produce detailed pictures of the inside of the body by aligning hydrogen atoms in the tissues. Magnetic resonance venography is now as accurate as contrast venography. Pulmonary embolism is diagnosed definitively by computed tomography (CT) scanning of the pulmonary arteries, which can show filling defects in the pulmonary arteries (Figure 57.34). Pulmonary angiography is rarely required unless interventional treatment is being considered. Radionuclide imaging has now been superseded by CT pulmonary angiography and should not normally be used. The differential diagnosis of a deep vein thrombosis includes a ruptured Baker’s cyst, a calf muscle haematoma, a ruptured plantaris muscle, a thrombosed popliteal aneurysm and arterial ischaemia. Duplex scanning will detect many of these conditions but often patients present with non-specific pain in the calf that resolves with no firm diagnosis being made. The differential

Figure 57.34 A computed tomography scan showing pulmonary emboli as filling defects (arrow) in the pulmonary artery.

diagnosis of a pulmonary embolism includes myocardial infarction, pleurisy and pneumonia.

Prophylaxis

Patients who are being admitted for surgery can be graded as low, moderate or high risk (Table 57.4). Patients in the medium or high risk groups should be considered for anticoagulation prophylaxis. Prophylactic methods can be divided into mechanical and pharmacological. A variety of mechanical methods have been tried but only the use of graduated elastic compression stockings and external pneumatic compression have been shown to be worthwhile by reducing the incidence of thrombosis.

Table 57.4 Low-, medium- and high-risk patient groups for deep vein thrombosis and pulmonary embolism.

Risk groups	
Low	Minor surgery <30 minutes. Any age. No risk factors
	Major surgery >30 minutes. Age <40. No other risk factors
	Minor trauma or medical illness, any age. No risk factors
Moderate	Major surgery. Age 40+ or other risk factors
	Major medical illness: heart/lung disease, cancer, inflammatory bowel disease
	Major trauma/burns
High	Minor surgery, trauma, medical illness in patient with previous DVT, PE or thrombophilia
	Major orthopaedic surgery or fracture pelvis, hip, lower limb
	Major abdominal/pelvic surgery for cancer
	Major surgery, trauma, medical illness in patient with DVT, PE or thrombophilia
Lower limb paralysis (e.g. stroke, paraplegia)	
Major lower limb amputation	

DVT, deep venous thrombosis; PE, pulmonary embolism.

Pharmacological methods are more effective than mechanical methods at risk reduction although they carry an increased risk of bleeding. In the past, low-dose unfractionated heparin was used both intravenously and subcutaneously. Most patients now start on low molecular weight heparin given subcutaneously, with the dose based on the patient's weight. This does not require monitoring and has a reduced risk of heparin-induced thrombocytopenia. It can be given once a day and has a lower risk of bleeding complications. Unfractionated heparin and warfarin are now rarely used in the prophylaxis of deep vein thrombosis. A combination of mechanical and pharmacological treatment with heparin can be used in patients considered at high risk.

Treatment of a deep vein thrombosis

Patients who are confirmed to have a deep vein thrombosis on duplex imaging should be started on subcutaneous low molecular weight heparin and rapidly anticoagulated with warfarin unless there is a specific contraindication. Warfarin is usually started at a dose of 10 mg on day 1, 10 mg on day 2 and 5 mg on day 3. A prothrombin time taken on days 2 and 3 along with a warfarin dose algorithm guides the maintenance dose of warfarin.

The great majority of patients are treated with heparin and warfarin in this way. Thrombolysis should be considered, however, in patients with an iliac vein thrombosis, especially if they are seen early and the limb is extremely swollen. Very few surgeons now carry out surgical venous thrombectomy, although it may still be attempted in patients with threatened venous gangrene and phlegmasia cerulio dolens. If performed, a venous thrombectomy should be accompanied by an arteriovenous fistula to increase venous flow through the vein that has had the thrombus removed, however the results are, at best, modest.

During thrombolysis, tissue plasminogen activator (or more usually urokinase in the United States) is administered directly into the thrombus, either via the popliteal vein or by direct puncture in the groin. New devices are being marketed that physically disrupt the thrombus at the same time as local lysis is carried out. Some thrombi can be compressed by stent grafting, allowing the venous lumen to be opened, especially in the iliac region. This technique is most useful in patients who have a malignant cause for their venous obstruction.

Treatment of pulmonary embolus

Most pulmonary emboli can be treated by anticoagulation and observation but severe right heart strain and shortness of breath indicate the need for fibrinolytic treatment or radiologically guided catheter embolectomy. Rarely, patients who are on the point of cardiac arrest should undergo surgical pulmonary embolectomy.

Prophylaxis against pulmonary embolism

In patients who are considered at high risk of embolism or when anticoagulants are contraindicated, an inferior vena cava filter may be inserted to prevent the onward passage of any emboli. Filters can also be placed in patients who continue to have pulmonary emboli despite adequate anticoagulation. A large number of different types of filter are now available, some of which are removable (temporary filters). There are no good randomised trials to determine which filter is best.

Superficial thrombophlebitis

This is a superficial venous thrombosis. The term 'thrombophlebitis' implies a major inflammatory component; however, this is

rarely seen. Common causes include external trauma (especially to varicose veins), venepunctures and infusions of hyperosmolar solutions and drugs. The presence of an intravenous cannula for longer than 24–48 hours often leads to local thrombosis. Some systemic diseases, such as thromboangiitis obliterans (Buerger's disease) and malignancy, especially of the pancreas, can lead to a flitting thrombophlebitis (thrombophlebitis migrans), affecting different veins at different times. Finally, coagulation disorders, such as polycythaemia, thrombocytosis and sickle cell disease are often associated, as is a concomitant thrombosis within the deep veins.

The surface vein feels solid and is tender on palpation. The overlying skin may be attached to the vein and in the early stages may be erythematous before gradually turning brown. A linear segment of vein of variable length can be easily palpated once the inflammation has died down.

A full blood count, coagulation screen and duplex scan of the deep veins should usually be obtained. Any suggestion of an associated malignancy should be investigated using appropriate endoscopy and imaging studies, such as an abdominal CT scan.

Most patients are treated with NSAIDs and the condition resolves spontaneously. Rarely, infected thrombi require incision or excision. Ligation to prevent propagation into the deep veins is almost never required, although some authors advocate saphenofemoral ligation when the thrombus is seen on ultrasound to be at the saphenofemoral junction. Associated deep vein thrombosis or thrombophilias are treated by anticoagulation.

LEG ULCERATION

Venous disease is responsible for between 60 and 70 per cent of all ulcers in the lower leg. There are many other causes of leg ulcers and these must be excluded in any patient presenting with ulceration:

- venous disease: superficial incompetence; deep venous damage (post-thrombotic);
- arterial ischaemic ulcers;
- rheumatoid ulcers;
- traumatic ulcers;
- neuropathic ulcers (diabetes);
- neoplastic ulcers (squamous cell carcinoma and basal cell carcinoma);
- infections, especially in Third World countries.

Up to 20 per cent of patients have evidence of arterial disease, which may be the sole cause of ulceration or may be a mixed factor in the development of an ulcer in association with venous disease.

Aetiology of ulceration

The exact pathophysiology of ulcer development has not been established. Originally, it was thought that static blood within the superficial veins led to hypoxia, which caused tissue death (stasis ulcers). This was not confirmed by investigation of venous oxygen saturation, which was found to be higher in ulcerated limbs. This led to the concept of arteriovenous fistulae, which were thought to develop in response to the high venous pressure; however, this could not be confirmed. High venous pressure was found to be associated with a pericapillary infiltrate. This includes fibrin and other proteins, which are known to lead to fibrosis. It was hypothesised that these 'cuffs' could act as a diffusion block.

Leukocytes were found to decrease in the venous effluent coming out of dependent limbs. This decrease in leukocyte passage was shown to increase if short-term venous hypertension was induced by application of a tourniquet. This led to the concept of white cell 'trapping', which, however, has not been confirmed by further investigation. Polymorphonuclear leukocytes were not found within the tissues but increased numbers of mast cells, monocytes and lymphocytes have been found in per ulcer tissues.

Reactive oxygen species are increased in the ulcer environment and these may generate free radicals, leading to tissue damage. Proteolytic enzymes are also increased in ulcers and the fibroblasts in the ulcer surrounds are also abnormal, being in a 'senescent' state. Growth factors may be inhibited, leading to poor repair, and their absence may also lead to ulceration. It is proving difficult to show whether any of these factors is the cause of or the result of an ulcer.

At present, ambulatory venous hypertension is the only accepted underlying cause of ulceration. This also explains why venous ulcers are never seen in the upper limb. It is important to try and define the exact mechanism of ulcer development. Venous hypertension may be the result of primary valve incompetence of the saphenous veins, incompetence of the perforating veins or incompetence or obstruction of the deep veins.

Clinical features

The ulcer must be carefully examined. A venous ulcer usually has a gently sloping edge and the floor contains granulation tissue covered by a variable amount of slough and exudate. Any significant elevation of the ulcer edge should indicate the need for a biopsy to exclude a carcinoma (usually a squamous cell).

The venous ulcer of the leg characteristically develops in the skin of the gaiter region, the area between the muscles of the calf and the ankle. This is the region where many of the Cockett perforators join the posterior tibial vein to the surface vein, known as the posterior arch vein. The majority of ulcers develop on the medial side of the calf but ulcers associated with lesser saphenous incompetence may develop on the lateral side of the leg. Ulcers can develop on any part of the calf skin in patients with post-thrombotic legs; however, venous ulcers rarely extend onto the foot or into the upper calf and, if there is ulceration at these sites, other diagnoses should be seriously considered. Ulcers often develop in response to minor trauma; many patients notice some itching, perhaps associated with mast cell degranulation, before the ulcers develop. Almost all venous ulcers have surrounding haemosiderosis (seen as pigmentation) and the more chronic ulcers develop lipodermatosclerosis with associated fibrosis of the subcutaneous tissue (Figure 57.10). This is manifest as thickening, pigmentation, inflammation and induration of the calf skin. The pigmentation comes from haemosiderin and melanin and the haemosiderin itself may be an important factor in the ulcer development.

A full examination of the front and back of the limbs with the patient standing should be carried out to assess the presence of varicosities and truncal incompetence of the saphenous systems (note that venous ulcers are not always accompanied by varicose veins).

All patients should have their pulses palpated and, if there is any doubt, their Doppler pressures should be measured. Sensation and proprioception should be assessed to exclude

neuropathy, especially in diabetic patients. A careful examination of the hand and other joints may confirm the presence of rheumatoid arthritis or osteoarthritis.

Investigation

Most vascular surgeons will carry out a duplex scan when the patient with an ulcer is first seen to assess the state of the deep and superficial veins. The presence of reflux in these veins does not confirm a venous ulcer but supports the diagnosis in the absence of another cause and helps direct treatment.

All patients presenting for the first time with a new leg ulcer should have a full blood count, blood glucose, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) and sickle cell test if they have an appropriate racial background. Anaemia can both cause ulcers (e.g. sickle cell disease and pernicious anaemia) and be a result of ulceration (e.g. iron deficiency anaemia and the anaemia of chronic disease). Polycythaemia is a rare cause of ulceration. An antibody screen should be obtained if the ulcer appears 'atypical' or there is any suggestion of joint disease (e.g. rheumatoid arthritis). All patients presenting with a new ulcer should have their Doppler pressures measured, unless the foot pulses are easily palpable and have been confirmed as such by a vascular specialist.

Management

When the diagnosis of a 'probable venous ulcer' has been made, patients are initially treated by a compression bandaging regimen, which can be applied in a specialised clinic or by a trained district or practice nurse. Patients with new ulcers should ideally be assessed in a specialised ulcer clinic to confirm the diagnosis and agree the correct treatment regimen.

Many bandaging regimens have been described but three types usually suffice. A multilayered elastic compression bandaging system has been shown to be effective (Charing Cross four-layer bandage), as has a rigid multilayered system (Steripaste™ three-layer bandage). A low-compression regimen is desirable for mixed venous/arterial ulcers. The alternative to these bandaging regimens is to apply a bland absorbent leak-proof dressing beneath a graduated elastic compression stocking (class II). Recent data suggest that this regimen may be equally effective in attaining ulcer healing.

These compression regimens are ideally applied by trained staff on a bi-weekly or weekly basis until the ulcer is starting to heal and the amount of exudate is reduced. Longer periods between dressing changes can then be instituted. At each attendance ulcer size must be measured to monitor improvement. Antibiotics do not speed ulcer healing in the absence of cellulitis and all other specific ulcer-healing drugs are of dubious validity. Failure to heal an ulcer may indicate that it has another or coexisting cause (e.g. malignancy, rheumatoid arthritis or arterial ischaemia). Biopsies are indicated if malignancy is suspected and it is important to remember that a Marjolin's type of ulcer (a squamous cell or basal cell carcinoma) can develop in a chronic long-standing venous ulcer (Figure 57.35).

Once these factors have been excluded, consideration may be given to healing the ulcer by excision and grafting in appropriate cases. A number of biological dressings have been developed, including fetal keratinocytes and collagen meshes, which have been shown to improve healing; however, they are not cost-effective for the majority of ulcers. Pinch grafts and

A gaiter is a leather or cloth covering for the lower leg and ankle. The name is derived from the French 'guêtre' for the same piece of clothing.

Frank Bernard Cockett, formerly surgeon, St Thomas's Hospital, London, UK.

Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

Charing Cross. This method of treating venous ulcers was introduced at Charing Cross Hospital, London, UK.

Figure 57.35 A Marjolin's ulcer (a squamous cell cancer arising in a chronic venous ulcer; arrow).

ulcer excision with mesh grafting have been shown to provide good early healing with moderate long-term results (50 per cent healed at five years).

The Eschar trial has confirmed that surgery to sites of superficial venous incompetence does not speed ulcer healing and this practice should be abandoned unless new evidence is provided of its efficacy.

Prevention of recurrence

Once an ulcer has healed the patient must be re-evaluated in an attempt to prevent recurrence. Patients with normal deep veins should be offered treatment to obliterate any sites of saphenous or perforator reflux. The Eschar study has confirmed the results of other studies showing that this treatment is effective in reducing the incidence of ulcer recurrence in patients with **normal** deep veins. Some patients will decline treatment and others will be considered unsuitable for major interventions on their veins.

Elastic stockings (normally class II) should be prescribed for all patients with evidence of post-thrombotic deep vein damage and these remain an alternative treatment for patients with superficial venous disease who decline intervention. Although ideally these should be above-knee stockings in many cases, the pragmatist will prescribe below-knee stockings as most patients will otherwise not comply. Stockings need to be worn during the day and are a lifelong prescription. Used effectively, they will reduce the incidence of any further DVTs and reduce although not eliminate the chance of further ulceration. Studies are required to determine whether laser ablation and foam sclerotherapy are as satisfactory as surgery in achieving prolonged ulcer-free periods.

Prognosis

Nearly all venous ulcers can be healed but, even in those who have successful surgery or wear their stockings religiously, there is a 20–30 per cent incidence of reulceration by five years. The greatest risk of reulceration is in the post-thrombotic leg.

CONGENITAL VENOUS ANOMALIES

There are four main types of anomaly:

- 1 aplasia;
- 2 hypoplasia;
- 3 duplication;
- 4 persistence of vestigial vessels.

Aplasia is most commonly seen in the inferior vena cava and has a similar presentation to the post-thrombotic limb. Membranous occlusion of the left common iliac vein (May–Thurner–Cockett syndrome) often develops where the vein passes behind the right common iliac artery (iliac vein compression syndrome). This leads to an iliac vein thrombosis, which most commonly affects the left common and external iliac veins. Membranes may also narrow the hepatic veins, which can become totally occluded, leading to a Budd–Chiari syndrome.

Hypoplasia results in a narrow vein.

Duplications are quite common, with double vena cava, femoral and renal veins; they often present as an incidental finding.

Klippel–Trenaunay syndrome

This is a combined anomaly of a cutaneous naevus, persistent vestigial veins with varicose veins, and soft tissue and bone hypertrophy. The condition is a mesodermal abnormality that is not familial (Figure 57.36).

Segments of the deep veins are hypoplastic or aplastic and there may be an associated obstruction of the lymphatics. The condition must be distinguished from the Parkes Weber syndrome, in which there are multiple arteriovenous fistulae causing venous hypertension, ulceration and high-output cardiac failure.

Virtually all patients with Klippel–Trenaunay syndrome should be treated conservatively with elastic compression hosiery; however, some will benefit from laser ablation of the naevus, stapling of the bones to avoid leg length discrepancy and occasional removal of large superficial varicose veins, provided the deep veins are normal. Low molecular weight heparin should be given to all patients having surgery as this syndrome is associated with an increased risk of deep vein thrombosis.

ENTRAPMENT OF VEINS

The axillary vein and the popliteal vein are the two veins that are most commonly compressed. The former is compressed at the thoracic outlet between the first rib and the clavicle, where it usually presents as an axillary vein thrombosis (see below) (Figure 57.37a). The latter is compressed by an abnormal insertion of the gastrocnemius muscles. Entrapment may cause discomfort and swelling of the limb during exercise before thrombosis develops. Treatment is by surgical decompression, excising the first rib or dividing the abnormal musculature of the gastrocnemius insertion.

AXILLARY VEIN THROMBOSIS

Thrombosis of the axillary vein may occur following excessive exercise in a patient with an anatomically abnormal thoracic outlet but is also associated with excessive muscle bulk as found

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France after the end of World War I, in 1918), gave his account of this condition in 1898.

Figure 57.36 Two patients with Klippel–Trenaunay syndrome. (a) This patient has a longer leg and a capillary naevus. (b) This patient has a large lateral anomalous axial vein.

in weightlifters. The vein may be compressed by a cervical rib if this is present (Figure 57.37b). The arm is swollen and painful and, at an early stage, the thrombus can be removed by thrombolysis delivered through one of the arm veins. The vein must then be imaged to see if there is any compression on elevation of the arm. Thoracic outlet decompression can be carried out by resecting the cervical rib or first rib if this is confirmed.

VENOUS INJURY

Blunt or penetrating trauma almost always damages some small and medium-sized veins, which can be safely ignored or ligated without causing any problems. Larger axial venous channels

Henry IV of Navarre, 1553–1610, led his army into the Battle of Ivry, shouting ‘rally round the white plume of Navarre’. He used his sword to such good effect that he could not use his arm for 6 weeks probably from an axillary vein thrombosis.

have, in the past, been ligated when injured, but it is now recognised that these axial veins should be repaired whenever possible to reduce subsequent morbidity (pain and swelling in the tissues being drained) and limb loss when associated with a concomitant arterial injury. Many venous injuries remain undiagnosed at the time of injury (e.g. crural vein damage associated with a fractured tibia) and only present many years later when post-thrombotic changes become apparent. Venous injuries occur from both civilian and military trauma but the incidence of venous military injuries has been particularly well documented. In total, 40–50 per cent of arterial injuries have concomitant venous injuries, especially in the popliteal fossa.

Classification

Venous injuries may be lacerated, contused or torn apart by stretching (Figure 57.38). Iatrogenic injuries result from damage at the time of surgery and from punctures caused by catheter insertion by radiologists and physicians. Thrombosis, haemor-

Figure 57.37 Thoracic outlet syndrome. (a) Cervical ribs; (b) elevation of the arm causing occlusion of the axillary vein with collateral fillings. The patient has had previous surgery on the left side.

Figure 57.38 Types of venous damage. (a) Incision; (b) transection; (c) irregular laceration; (d) avulsion of a tributary.

rhage and embolisation are all common complications and arteriovenous fistulae may develop when a penetrating needle transfixes the vein and artery.

Associated injuries to soft tissue, arteries and bones often overshadow the venous injury. Massive haemorrhage from the pelvic bones or the inferior vena cava can rapidly lead to hypovolaemic shock and death if left untreated. Haematomas are common and engorgement, cyanosis and swelling are also indicative of a major venous injury.

Figure 57.39 Types of venous repair. (a) Lateral suture; (b) patch graft; (c) Carrel triangulation technique of venous anastomosis; (d) panel graft; (e) spiral graft.

Investigations are rarely helpful and rapid exploration is usually required except in the case of unstable pelvic fractures where external fixation has dramatically improved the outcome of these injuries by stabilising the injury. Embolisation and stent grafting can have a limited role, especially if the venous injury is relatively inaccessible or an arteriovenous fistula has developed.

The patient must be adequately resuscitated, have blood cross-matched and have good intravenous access obtained via a central venous pressure line if possible, provided that there are no injuries around the neck or thorax. Gentle wound exploration, under tourniquet control when possible, should assess the extent of the injuries before the vessels are dissected out and clamped. Different types of repair are shown in Figure 57.39; the type of repair carried out depends on the extent of the venous injury, including how much venous wall has been lost or damaged. Lateral sutures and vein patches are ideal methods of repair and end-to-end anastomosis is satisfactory provided that it is not carried out under tension.

Vein replacement should be by autogenous tissue whenever possible, using vein harvested from another site, e.g. the internal jugular vein or the long saphenous vein from an undamaged limb. Artificial grafts, such as polytetrafluoroethylene (PTFE) grafts, are likely to get infected in contaminated wounds and have given poor results in recent conflicts. The use of anti-coagulants and an arteriovenous fistula to reduce the risk of thrombosis in the vein graft are controversial and depend on the associated injuries that are present. In contaminated wounds, tetanus, toxoid and antibiotics should be given. A fasciotomy should always be considered if there is a concomitant arterial and venous injury.

Prognosis

It is now recognised that repair of a major axial vein can be carried out with a 70–80 per cent success rate, reducing the morbidity of a combined arterial and venous injury considerably (especially limb loss). Complex repairs should not, however, be carried out if a patient's life is at risk, when ligation may have to suffice in the short term.

VENOUS TUMOURS

Cystic degeneration of the vein wall is an uncommon cause of venous occlusion. It may be detected by ultrasound. The cyst may be deroofed or the venous segment excised.

Venous malformation cavernous angioma/haemangioma

These malformations are common, representing one end of a spectrum of arteriovenous malformations. They often affect the skin but also extend into the deep tissues, including bones and joints. They usually present with variable swelling and dilated veins beneath the skin. Occasionally, there is no visible mass and the complaint is one of pain. Haemorrhage and thrombophlebitis may exacerbate the pain. A soft compressible mass, which is venous in colour especially if it is under the skin, is usually present (Figure 57.40a). A dark blue tinge is often apparent even if the malformation is deeply situated. Nodules within the mass usually represent previous episodes of thrombosis. The size and extent of the haemangioma are best visualised by nuclear magnetic resonance with a short tau inversion recovery (STIR) sequence (Figure 57.40b) or CT scanning with contrast

Figure 57.40 (a) Venous angioma of the leg. (b) Magnetic resonance with a short tau inversion recovery sequence showing angioma in white throughout the limb.

enhancement. Venography rarely shows an abnormality, but direct puncture with contrast injection shows the connections of the malformation.

Treatment is a highly specialised area. Treatment options nowadays rarely initially involve surgical excision as once this is done future embolisation and sclerotherapy is very difficult. No treatment is entirely curative because it is difficult to remove all of the angiomatous tissue or sclerose the angioma completely. Sclerosis can be dangerous when the veins connect to the deep system, particularly near the central nervous system.

Leiomyomas and leiomyosarcomas of the vein wall

These are extremely rare tumours that are usually slow growing. They present with pain and a mass with signs of venous

obstruction, e.g. oedema and distended veins. Duplex scanning, CT (Figure 57.41) and magnetic resonance imaging show a filling defect within the vein wall. Treatment is by resection with replacement by autogenous vein taken from another site. Rarely, a PTFE graft is required. When the tumour affects the vena cava it must be resected and replaced with a prosthetic graft.

LEARNING OBJECTIVES

To understand:

- The main functions of the lymphatic system
- The development of the lymphatic system
- The various causes of limb swelling
- The aetiology, clinical features, investigations and treatment of lymphoedema

INTRODUCTION

The lymphatic system was first described by Erasistratus in Alexandria more than 2000 years ago. William Hunter, in the late eighteenth century, was the first to describe the function of the lymphatic system. Starling's pioneering work on the hydrostatic and haemodynamic forces controlling the movement of fluid across the capillary provided further insights into the function of the lymphatics. However, there is much about the lymphatic system that is not understood and debate continues over the precise aetiology of the most common abnormality of the system, namely lymphoedema.

ANATOMY AND PHYSIOLOGY OF THE LYMPHATIC SYSTEM**Functions**

The principal function of the lymphatics is the return of protein-rich fluid to the circulation through the lymphaticovenous junctions in the jugular area. Thus, water, electrolytes, low molecular weight moieties (polypeptides, cytokines, growth factors) and macromolecules (fibrinogen, albumin, globulins, coagulation and fibrinolytic factors) from the interstitial fluid (ISF) return to the circulation via the lymphatics. Intestinal lymph (chyle) transports cholesterol, long-chain fatty acids, triglycerides and the fat-soluble vitamins (A, D, E and K) directly to the circulation, bypassing the liver. Lymphocytes and other immune cells also circulate within the lymphatic system.

Development and macroanatomy

In the human embryo lymph sacs develop at 6–7 weeks' gestation as four cystic spaces, one on either side of the neck and one in each groin. These cisterns enlarge and develop communications that permit lymph from the lower limbs and abdomen to drain

via the cisterna chyli into the thoracic duct, which in turn drains into the left internal jugular vein at its confluence with the left subclavian vein. Lymph from the head and right arm drains via a separate lymphatic trunk, the right lymphatic duct, into the right internal jugular vein. Lymphatics accompany veins everywhere except in the cortical bony skeleton and central nervous system, although the brain and retina possess cerebrospinal fluid and aqueous humour, respectively.

The lymphatic system comprises lymphatic channels, lymphoid organs (lymph nodes, spleen, Peyer's patches, thymus, tonsils) and circulating elements (lymphocytes and other mononuclear immune cells). Lymphatic endothelial cells are derived from embryonic veins in the jugular and perimesonephric areas from where they migrate to form the primary lymph sacs and plexus. Both transcription (e.g. Prox1) and growth (e.g. VEGF-C) factors are essential for these developmental events.

Microanatomy and physiology**Lymphatic capillaries**

Lymphatics originate within the ISF space from specialised endothelialised capillaries (initial lymphatics) or non-endothelialised channels such as the spaces of Disse in the liver. Initial lymphatics are unlike arteriovenous capillaries in that:

- they are blind-ended;
- they are much larger (50 µm);
- they allow the entry of molecules of up to 1000 kDa in size because the basement membrane is fenestrated, tenuous or even absent and the endothelium itself possesses intra- and intercellular pores;
- they are anchored to interstitial matrix by filaments. In the resting state, initial lymphatics are collapsed. When ISF volume and pressure increases, initial lymphatics and their pores are held open by these filaments to facilitate increased drainage.

Terminal lymphatics

Initial lymphatics drain into terminal (collecting) lymphatics

William Hunter, 1718–1783, anatomist and obstetrician who became the first Professor of Anatomy at the Royal Academy of Arts, London, UK. He was the elder brother of John Hunter, the anatomist and surgeon.

Erasistratus of Chios, c.300–250 BC, of the Medical School at Alexandria in Egypt is regarded by many as the first physiologist.

Ernest Henry Starling, 1866–1927, Professor of Physiology, University College, London, UK.

Josef Disse, 1852–1912, a German anatomist.

that possess bicuspid valves and endothelial cells rich in the contractile protein actin. Larger collecting lymphatics are surrounded by smooth muscle. Valves partition the lymphatics into segments (lymphangions) that contract sequentially to propel lymph into the lymph trunks.

Lymph trunks

Terminal lymphatics lead to lymph trunks, which have a structure similar to that of veins, namely a single layer of endothelial cells, lying on a basement membrane overlying a media comprising smooth muscle cells that are innervated with sympathetic, parasympathetic and sensory nerve endings. About 10 per cent of lymph arising from a limb is transported in deep lymphatic trunks that accompany the main neurovascular bundles. The majority, however, is conducted against venous flow from deep to superficial in epifascial lymph trunks. Superficial trunks form lymph bundles of various sizes, which are located within strips of adipose tissue, and tend to follow the course of the major superficial veins.

Starling's forces

The distribution of fluid and protein between the vascular system and ISF depends on the balance of hydrostatic and oncotic pressures between the two compartments (Starling's forces), together with the relative impermeability of the blood capillary membrane to molecules over 70 kDa. In health there is net capillary filtration, which is removed by the lymphatic system.

Transport of particles

Particles enter the initial lymphatics through interendothelial openings and vesicular transport through intraendothelial pores. Large particles are actively phagocytosed by macrophages and transported through the lymphatic system intracellularly.

Mechanisms of lymph transport

Resting ISF is negative (-2 to -6 mmH₂O), whereas lymphatic pressures are positive, indicating that lymph flows against a small pressure gradient. It is believed that prograde lymphatic flow depends upon three mechanisms:

- 1 transient increases in interstitial pressure secondary to muscular contraction and external compression;
- 2 the sequential contraction and relaxation of lymphangions;
- 3 the prevention of reflux because of valves.

Lymphangions are believed to respond to increased lymph flow in much the same way as the heart responds to increased venous return in that they increase their contractility and stroke volume. Contractility is also enhanced by noradrenaline, serotonin, certain prostaglandins and thromboxanes, and endothelin-1. Pressures of up to 30–50 mmHg have been recorded in normal lymph trunks and up to 200 mmHg in severe lymphoedema. Lymphatics may also modulate their own contractility through the production of nitric oxide and other local mediators. Transport in the thoracic and right lymph ducts also depends upon intrathoracic (respiration) and central venous (cardiac cycle) pressures. Therefore, cardiorespiratory disease may have an adverse effect on lymphatic function.

In summary, in the healthy limb, lymph flow is largely due to intrinsic lymphatic contractility, although this is augmented by exercise, limb movement and external compression. However, in lymphoedema, when the lymphatics are constantly distended

with lymph, these external forces assume a much more important functional role.

ACUTE INFLAMMATION OF THE LYMPHATICS

Acute lymphangitis is an infection, often caused by *Streptococcus pyogenes* or *Staphylococcus aureus*, which spreads to the draining lymphatics and lymph nodes (lymphadenitis) where an abscess may form. Eventually this may progress to bacteraemia or septicaemia. The normal signs of infection (rubor, calor, dolor) are present and a red streak is seen in the skin along the line of the inflamed lymphatic (Figure 58.1). The part should be rested to reduce lymphatic drainage and elevated to reduce swelling, and the patient should be treated with intravenous antibiotics based upon actual or suspected sensitivities. Failure to improve within 48 hours suggests inappropriate antibiotic therapy, the presence of undrained pus or the presence of an underlying systemic disorder (malignancy, immunodeficiency). The lymphatic damage caused by acute lymphangitis may lead to recurrent attacks of infection and lymphoedema; patients with lymphoedema are prone to so-called acute inflammatory episodes (see below).

Figure 58.1 Acute lymphangitis of the arm. Erythematous streaks extend from the site of primary infection on the volar aspect of the forearm to epicondylar nodes at the elbow and from there to enlarged and tender axillary lymph nodes.

LYMPHOEDEMA

Definition

Lymphoedema may be defined as abnormal limb swelling caused by the accumulation of increased amounts of high protein ISF secondary to defective lymphatic drainage in the presence of (near) normal net capillary filtration.

The scope of the clinical problem

At birth, 1 in 6000 people will develop lymphoedema with an overall prevalence of 0.13–2 per cent. The condition is not only associated with significant physical symptoms and complications but is also a frequent cause of emotional and psychological distress, which can lead to difficulties with relationships, education and work (Summary box 58.1).

Despite this significant impact on quality of life, many sufferers choose not to seek medical advice because of embarrassment and a belief that nothing can be done. Patients who do come

Summary box 58.1**Symptoms frequently experienced by patients with lymphoedema**

- Swelling, clothing or jewellery becoming tighter
- Constant dull ache, even severe pain
- Burning and bursting sensations
- General tiredness and debility
- Sensitivity to heat
- 'Pins and needles'
- Cramp
- Skin problems, including flakiness, weeping, excoriation and breakdown
- Immobility, leading to obesity and muscle wasting
- Backache and joint problems
- Athlete's foot
- Acute infective episodes

forward for help, especially those with non-cancer-related lymphoedema, often find they have limited access to appropriate expertise and treatment. Lymphoedema is often misdiagnosed and mistreated by doctors, who frequently have a poor understanding of the importance of the condition, believing it to be primarily a cosmetic problem in the early stages. However, making an early diagnosis is important because relatively simple measures can be highly effective at this stage and can prevent the development of disabling late disease, which is often very difficult to treat. It is also an opportunity for patients to make contact with patient support groups (Summary box 58.2).

Summary box 58.2**What every patient with lymphoedema should receive**

- An explanation of why the limb is swollen and the underlying cause
- Guidance on skin hygiene and care and the avoidance of acute infective episodes
- Antifungal prophylactic therapy to prevent athlete's foot
- Rapid access to antibiotic therapy if necessary, hospital admission for acute infective episodes
- Appropriate instructions regarding exercise therapy
- Manual lymphatic drainage (MLD)
- Multilayer lymphoedema bandaging (MLLB)
- Compression garments and, if appropriate, specialised footwear
- Advice on diet
- Access to support services and networks

The severity of unilateral limb lymphoedema can be classified as:

- mild: <20 per cent excess limb volume;
- moderate: 20–40 per cent excess limb volume;
- severe: >40 per cent excess limb volume.

Pathophysiology

The ISF compartment (10–12 litres in a 70-kg man) constitutes 50 per cent of the wet weight of the skin and subcutaneous

tissues and, in order for oedema to be clinically detectable, its volume has to double. About 8 litres (protein concentration approximately 20–30 g/L, similar to ISF) of lymph is produced each day and travels in afferent lymphatics to lymph nodes. There, the volume is halved and the protein concentration doubled, resulting in 4 litres of lymph re-entering the venous circulation each day via efferent lymphatics. In one sense, all oedema is lymphoedema in that it results from an inability of the lymphatic system to clear the ISF compartment. However, in most types of oedema this is because the capillary filtration rate is pathologically high and overwhelms a normal lymphatic system, resulting in the accumulation of low-protein oedema fluid. In contrast, in true lymphoedema, when the primary problem is in the lymphatics, capillary filtration is normal and the oedema fluid is relatively high in protein. Of course, in a significant number of patients with oedema there is both abnormal capillary filtration and abnormal lymphatic drainage, as in chronic venous insufficiency (CVI) for example.

Lymphoedema results from lymphatic aplasia, hypoplasia, dysmotility (reduced contractility with or without valvular insufficiency), obliteration by inflammatory, infective or neoplastic processes, or surgical extirpation. Whatever the primary abnormality, the resultant physical and/or functional obstruction leads to lymphatic hypertension and distension, with further secondary impairment of contractility and valvular competence. Lymphostasis and lymphotension lead to the accumulation in the ISF of fluid, proteins, growth factors and other active peptide moieties, glycosaminoglycans and particulate matter, including bacteria. As a consequence, there is increased collagen production by fibroblasts, an accumulation of inflammatory cells (predominantly macrophages and lymphocytes) and activation of keratinocytes. The end result is protein-rich oedema fluid, increased deposition of ground substance, subdermal fibrosis and dermal thickening and proliferation. Lymphoedema, unlike all other types of oedema, is confined to the epifascial space. Although muscle compartments may be hypertrophied because of the increased work involved in limb movement, they are characteristically free of oedema.

Classification

Two main types of lymphoedema are recognised:

- 1 **Primary lymphoedema**, in which the cause is unknown (or at least uncertain and unproven); it is thought to be caused by 'congenital lymphatic dysplasia'.
- 2 **Secondary or acquired lymphoedema**, in which there is a clear underlying cause.

Primary lymphoedema is usually further subdivided on the basis of the presence of family history, age of onset and lymphangiographic findings (Tables 58.1 and 58.2) (see below).

Risk factors for lymphoedema

Although the true risk factor profile for lymphoedema is not currently known, a number of factors are thought to predispose an individual to its development and predict progression, severity and outcome of the condition (Table 58.3).

Symptoms and signs

In most cases, the diagnosis of primary or secondary lymphoedema can be made and the condition can be differentiated from other causes of a swollen limb on the basis of history and exami-

Table 58.1 Aetiological classification of lymphoedema.

Primary lymphoedema	Congenital (onset <2 years old): sporadic; familial (Nonne–Milroy’s disease) Praecox (onset 2–35 years old): sporadic; familial (Letessier–Meige’s disease) Tarda (onset after 35 years old)
Secondary lymphoedema	Parasitic infection (filariasis) Fungal infection (tinea pedis) Exposure to foreign body material (silica particles) Primary lymphatic malignancy Metastatic spread to lymph nodes Radiotherapy to lymph nodes Surgical excision of lymph nodes Trauma (particularly degloving injuries) Superficial thrombophlebitis Deep venous thrombosis

Table 58.2 Clinical classification of lymphoedema.

Grade (Brunner)	Clinical features
Subclinical (latent)	There is excess interstitial fluid and histological abnormalities in lymphatics and lymph nodes, but no clinically apparent lymphoedema
I	Oedema pits on pressure and swelling largely or completely disappears on elevation and bed rest
II	Oedema does not pit and does not significantly reduce upon elevation, positive Stemmer’s sign
III	Oedema is associated with irreversible skin changes, i.e. fibrosis, papillae

nation without recourse to complex investigation (Table 58.4). Unlike other types of oedema, lymphoedema characteristically involves the foot (Figure 58.2). The contour of the ankle is lost through infilling of the submalleolar depressions, a ‘buffalo hump’ forms on the dorsum of the foot, the toes appear ‘square’ because of confinement of footwear and the skin on the dorsum of the toes cannot be pinched because of subcutaneous fibrosis (Stemmer’s sign). Lymphoedema usually spreads proximally to knee level and less commonly affects the whole leg (Figure 58.3). In the early stages, lymphoedema will ‘pit’ and the patient will report that the swelling is down in the morning. This represents a reversible component to the swelling, which can be controlled. Failure to do so allows fibrosis, dermal thickening and hyperkeratosis to occur. In general, primary lymphoedema progresses more slowly than secondary lymphoedema. Chronic eczema fungal infection of the skin (dermatophytosis) and nails (onychomycosis), fissuring, verrucae and papillae (warts) are frequently seen in advanced disease. Ulceration is unusual, except in the presence of chronic venous insufficiency.

Figure 58.2 The foot of a patient with typical lymphoedema.

Figure 58.3 The lower leg of a patient with typical lymphoedema.

Table 58.3 Risk factors for lymphoedema.

Upper limb/trunk lymphoedema	Lower limb lymphoedema
Surgery with axillary lymph node dissection, particularly if extensive breast or lymph node surgery	Surgery with inguinal lymph node dissection
Scar formation, fibrosis and radiodermatitis from postoperative axillary radiotherapy	Postoperative pelvic radiotherapy
Radiotherapy to the breast or to the axillary, internal mammary or subclavicular lymph nodes	Recurrent soft tissue infection at the same site
Drain/wound complications or infection	Obesity
Cording (axillary web syndrome)	Varicose vein stripping and vein harvesting
Seroma formation	Genetic predisposition/family history of chronic oedema
Advanced cancer	Advanced cancer
Obesity	Intrapelvic or intra-abdominal tumours that involve or directly compress lymphatic vessels
Congenital predisposition	Orthopaedic surgery
Trauma in an 'at-risk' arm (venepuncture, blood pressure measurement, injection)	Poor nutritional status
Chronic skin disorders and inflammation	Thrombophlebitis and chronic venous insufficiency, particularly post-thrombotic syndrome
Hypertension	Any unresolved asymmetrical oedema
Taxane chemotherapy	Chronic skin disorders and inflammation
Insertion of pacemaker	Concurrent illnesses such as phlebitis, hyperthyroidism, kidney or cardiac disease
Arteriovenous shunt for dialysis	Immobilisation and prolonged limb dependency
Air travel	Air travel
Living in or visiting an area for endemic lymphatic filariasis	Living in or visiting an area for endemic lymphatic filariasis

Lymphangiomas are dilated dermal lymphatics that 'blister' onto the skin surface. The fluid is usually clear but may be blood-stained. In the long term, lymphangiomas thrombose and fibrose, forming hard nodules that may raise concerns about malignancy. If lymphangiomas are <5 cm across, they are termed lymphangioma circumscriptum, and if they are more widespread, they are termed lymphangioma diffusum. If they form a reticulate pattern of ridges then it has been termed lymphoedema *ab igne*. Lymphangiomas frequently weep (lymphorrhoea, chylothorax), causing skin maceration, and they act as a portal for infection. Protein-losing diarrhoea, chylous ascites, chylothorax, chyluria and discharge from lymphangiomas suggest lymphangectasia (megalymphatics) and chylous reflux.

Ulceration, non-healing bruises and raised purple-red nodules should lead to suspicion of malignancy. Lymphangiosarcoma was originally described in postmastectomy oedema (Stewart–Treves' syndrome) and affects around 0.5 per cent of patients at a mean onset of ten years. However, lymphangiosarcoma can develop in any long-standing lymphoedema, but usually takes longer to

manifest (20 years). It presents as single or multiple bluish/red skin and subcutaneous nodules that spread to form satellite lesions, which may then become confluent. The diagnosis is usually made late and confirmed by skin biopsy. Amputation offers the best chance of survival but, even then, most patients live for less than three years. It has been suggested that lymphoedema leads to an impairment of immune surveillance and so predisposes to other malignancies, although the causal association is not as definite as it is for lymphangiosarcoma (Summary box 58.3).

Summary box 58.3

Malignancies associated with lymphoedema

- Lymphangiosarcoma (Stewart–Treves' syndrome)
- Kaposi's sarcoma (HIV)
- Squamous cell carcinoma
- Liposarcoma
- Malignant melanoma
- Malignant fibrous histiocytoma
- Basal cell carcinoma
- Lymphoma

Fred Waldorf Stewart, 1894–1991, Chairman of Pathology, Memorial Sloan-Kettering Hospital, New York, NY, USA. An annual award was instituted in his name by the Department of Pathology called the Fred Waldorf Stewart Award.

Ab igne is Latin for 'from fire'.

William Marrant Baker, 1839–1896, surgeon, St Bartholomew's Hospital, London, UK, described these cysts in 1877.

Norman Treves, 1894–1964, an American surgeon. He had a special interest in male breast cancer.

Stewart and Treves reported this condition in a joint paper in 1948.

Table 58.4 Differential diagnosis of the swollen limb.

Non-vascular or lymphatic	General disease states	Cardiac failure from any cause Liver failure Hypoproteinaemia due to nephrotic syndrome, malabsorption, protein-losing enteropathy Hypothyroidism (myxoedema) Allergic disorders, including angioedema and idiopathic cyclic oedema Prolonged immobility and lower limb dependency
	Local disease processes	Ruptured Baker's cyst Myositis ossificans Bony or soft-tissue tumours Arthritis Haemarthrosis Calf muscle haematoma Achilles tendon rupture
	Retroperitoneal fibrosis	May lead to arterial, venous and lymphatic abnormalities
	Gigantism	Rare All tissues are uniformly enlarged
	Drugs	Corticosteroids, oestrogens, progestagens Monoamine oxidase inhibitors, phenylbutazone, methyl dopa, hydralazine, nifedipine
	Trauma	Painful swelling due to reflex sympathetic dystrophy
	Obesity	Lipodystrophy Lipoidosis
	Deep venous thrombosis	There may be an obvious predisposing factor, such as recent surgery The classical signs of pain and redness may be absent
	Post-thrombotic syndrome	Swelling, usually of the whole leg, due to iliofemoral venous obstruction Venous skin changes, secondary varicose veins on the leg and collateral veins on the lower abdominal wall Venous claudication may be present
	Varicose veins	Simple primary varicose veins are rarely the cause of significant leg swelling
Venous	Klippel–Trenaunay's syndrome and other malformations	Rare Present at birth or develops in early childhood Comprises an abnormal lateral venous complex, capillary naevus, bony abnormalities, hypo(a)plasia of deep veins and limb lengthening Lymphatic abnormalities often coexist
	External venous compression	Pelvic or abdominal tumour including the gravid uterus Retroperitoneal fibrosis
	Ischaemia–reperfusion	Following lower limb revascularisation for chronic and particularly chronic ischaemia
	Arteriovenous malformation	May be associated with local or generalised swelling
	Aneurysm	Popliteal Femoral False aneurysm following (iatrogenic) trauma

PRIMARY LYMPHOEDEMA

Aetiology

It has been proposed that all cases of primary lymphoedema are due to an inherited abnormality of the lymphatic system, sometimes termed 'congenital lymphatic dysplasia'. However, it is possible that many sporadic cases of primary lymphoedema occur in the presence of a (near-)normal lymphatic system and are actually examples of secondary lymphoedema for which the triggering events have gone unrecognised. These might

include seemingly trivial (but repeated) bacterial and/or fungal infections, insect bites, barefoot walking (silica), deep venous thrombosis (DVT) or episodes of superficial thrombophlebitis. In animal models, simple excision of lymph nodes and/or trunks leads to acute lymphoedema, which resolves within a few weeks, presumably because of the development of collaterals. The human condition can only be mimicked by inducing extensive lymphatic obliteration and fibrosis. Even then, there may be considerable delay between the injury and the onset of oedema. Primary lymphoedema is much more common in the legs than the arms. This may be because of gravity and a bipedal posture,

the fact that the lymphatic system of the leg is less well developed, or the increased susceptibility of the leg to trauma and/or infection. Furthermore, loss of the venoarteriolar reflex (VAR), which protects lower limb capillaries from excessive hydrostatic forces in the erect posture, with age and disease (CVI, diabetes), may be important.

Classification

Primary lymphoedema is usually classified on the basis of apparent genetic susceptibility, age of onset or lymphangiographic findings. None of these is ideal and the various classification systems in existence can appear confusing and conflicting as various terms and eponyms are used loosely and interchangeably. This has hampered research and efforts to gain a better understanding of underlying mechanisms, the effectiveness of therapy and prognosis.

Genetic susceptibility

Primary lymphoedema is often subdivided into those cases in which there appears to be a genetic susceptibility or element to the disease, and those in which there is not. The former may be further divided into those cases that are familial (hereditary), when typically the only abnormality is lymphoedema and there is a family history, and those cases that are syndromic, when the lymphoedema is only one of several congenital abnormalities and is either inherited or sporadic. Syndromic lymphoedema may be sporadic and chromosomal (Turner's (XO karyotype), Klinefelter's (XXY), Down's (trisomy 21) syndrome) or clearly inherited and related to an identified or presumed single-gene defect (lymphoedema–distichiasis (autosomal dominant defect in *FOXC2* gene)), or of uncertain genetic aetiology (yellow-nail and Klippel–Trenaunay–Weber's syndromes). Familial (hereditary) lymphoedema can be difficult to distinguish from non-familial lymphoedema because a reliable family history may be unobtainable, the nature of the genetic predisposition is unknown and the genetic susceptibility may only translate into clinical disease in the presence of certain environmental factors. Although the distinction may not directly affect treatment, the patients are often concerned lest they be 'passing on' the disease to their children.

Two main forms of familial (hereditary) lymphoedema are recognised – Nonne–Milroy (type I) and Letessier–Meige (type II) – although it is likely that both eponymous diseases overlap and represent more than a single disease entity and genetic abnormality. Milroy's disease is estimated to be present in 1 in 6000 live births and is probably inherited in an autosomal dominant manner with incomplete (about 50 per cent) penetrance. In some families, the condition may be related to abnormalities in the gene coding for a vascular endothelial growth factor receptor 3 (VEGFR3) on chromosome 5. The disease is characterised by brawny lymphoedema of both legs (and sometimes the genitalia, arms and face), which develops from birth or before puberty. The disease has been associated with a wide range of lymphatic abnormalities on lymphangiography. Meige's disease is similar to Milroy's disease, except that the lymphoedema generally develops between puberty and middle age (50 years). It usually affects one or both legs but may involve the arms. Some, but not all, cases appear to be inherited in an autosomal dominant manner. Lymphangiography generally shows aplasia or hypoplasia.

Age of onset

Lymphoedema congenita (onset at or within two years of birth) is more common in males and is more likely to be bilateral and involve the whole leg. Lymphoedema praecox (onset from 2 to 35 years) is three times more common in females, has a peak incidence shortly after menarche, is three times more likely to be unilateral than bilateral and usually only extends to the knee. Lymphoedema tarda develops, by definition, after the age of 35 years and is often associated with obesity, with lymph nodes being replaced with fibrofatty tissue. The cause is unknown. Lymphoedema developing for the first time after 50 years should prompt a thorough search for underlying (pelvic, genitalia) malignancy. It is worth noting that, in such patients, lymphoedema often commences proximally in the thigh rather than distally (Figure 58.4).

Lymphangiographic classification

Browse has classified primary lymphoedema on the basis of lymphangiographic findings (Table 58.5 and Figures 58.5 and 58.6). These findings may be related to the clinical presentations described above. Some patients with lymphatic hyperplasia possess megalymphatics in which lymph or chyle refluxes freely under the effects of gravity against the physiological direction of flow. The megalymphatics usually end in thin-walled vesicles on the skin, serous surfaces (chylous ascites, chylothorax), intestine (protein-losing enteropathy), kidney or bladder (chyluria) (Figure 58.7).

SECONDARY LYMPHOEDEMA

This is the most common form of lymphoedema. There are several well-recognised causes including infection, inflammation, neoplasia and trauma (Table 58.6).

Figure 58.4 This patient, in her sixth decade, presented with rapid onset of lymphoedema of the right leg. On further investigation she was found to have locally advanced bladder carcinoma. Note that unlike most cases of lymphoedema the swelling is greater proximally than distally.

Sir Norman Leslie Browse, formerly Professor of Surgery, the United Medical and Dental Schools of Guy's and St Thomas's Hospitals, London, UK; former President of the Royal College of Surgeons of England.

Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, OK, USA.

Harry Fitch Klinefelter, Jr, born 1912, Associate Professor of Medicine, The Johns Hopkins University Medical School, Baltimore MD, USA, described this syndrome in 1942.

John Langdon Haydon Down (sometimes given as **Langdon-Down**), 1828–1896, physician, The London Hospital, London, UK.

Max Nonne, 1861–1959, a neurologist of Hamburg, Germany, described this disease in 1891.

William Forsyth Milroy, 1855–1942, Professor of Clinical Medicine, Columbia University, New York, NY, USA, described the condition in 1892.

Henri Meige, 1866–1940, physician, La Salpêtrière, Paris, France, gave his description of the disease in 1899.

Table 58.5 Lymphangiographic classification of primary lymphoedema.

	Congenital hyperplasia (10%)	Distal obliteration (80%)	Proximal obliteration (10%)
Age of onset	Congenital	Puberty (praecox)	Any age
Sex distribution	Male > female	Female > male	Male = female
Extent	Whole leg	Ankle, calf	Whole leg, thigh only
Laterality	Unilateral = bilateral	Often bilateral	Usually unilateral
Family history	Often positive	Often positive	No
Progression	Progressive	Slow	Rapid
Response to compression therapy	Variable	Good	Poor
Comments	Lymphatics are increased in number; although functionally defective, there is usually an increased number of lymph nodes. May have chylous ascites, chylothorax and protein-losing enteropathy	Absent or reduced distal superficial lymphatics. Also termed aplasia or hypoplasia	There is obstruction at the level of the aortoiliac or inguinal nodes. If associated with distal dilatation, the patient may benefit from lymphatic bypass operation. Other patients have distal obliteration as well

Filariasis

This is the most common cause of lymphoedema worldwide, affecting up to 100 million individuals. It is particularly prevalent in Africa, India and South America where 5–10 per cent of the population may be affected. The viviparous nematode *Wucheria bancrofti*, whose only host is man, is responsible for 90 per cent of cases and is spread by the mosquito. The disease is associated with poor sanitation. The parasite enters lymphatics from the blood and lodges in lymph nodes, where it causes fibrosis and obstruction, due partly to direct physical damage and partly to the immune response of the host. Proximal lymphatics become grossly dilated with adult parasites. The degree of

oedema is often massive, in which case it is termed elephantiasis (Figure 58.8). Immature parasites (microfilariae) enter the blood at night and can be identified on a blood smear, in a centrifuged specimen of urine or in lymph itself. A complement fixation test is also available and is positive in present or past infection. Eosinophilia is usually present. Diethylcarbamazine destroys the parasites but does not reverse the lymphatic changes, although there may be some regression over time. Once the infection has been cleared, treatment is as for primary lymphoedema. Public health measures to reduce mosquito breeding, protective clothing and mosquito netting may be usefully employed to combat the condition (Summary box 58.4).

Figure 58.5 This patient presented with congenital lymphoedema of the right leg. The lymphangiogram shows lymphatic hypoplasia.

Figure 58.6 This patient presented with lymphoedema of the right leg. A bipedal lymphangiogram demonstrated normal lymphatics in the right leg up to the inguinal nodes, but no progression of contrast above the inguinal ligament – a case of proximal obstruction.

Figure 58.7 Lymphangiogram demonstrating reflux from dilated para-aortic vessels into the left kidney in a patient with filariasis who presented with chyluria.

Summary box 58.4

Features of filariasis

Acute

- Fever
- Headache
- Malaise
- Inguinal and axillary lymphadenitis
- Lymphangitis
- Cellulitis, abscess formation and ulceration
- Funiculo-epididymo-orchitis

Chronic

- Lymphoedema of legs (arm, breast)
- Hydrocoele
- Abdominal lymphatic varices
 - Chyluria
 - Lymphuria

Endemic elephantiasis (podoconiosis)

This is common in the tropics and affects more than 500 000 people in Africa. The barefoot cultivation of soil composed of alkaline volcanic rocks leads to destruction of the peripheral lymphatics by particles of silica, which can be seen in macrophages in draining lymph nodes. Plantar oedema develops in

Table 58.6 Classification of causes of secondary lymphoedema.

Classification	Example(s)
Trauma and tissue damage	Lymph node excision Radiotherapy Burns Varicose vein surgery/harvesting Large/circumferential wounds Scarring
Malignant disease	Lymph node metastases Infiltrative carcinoma Lymphoma Pressure from large tumours
Venous disease	Chronic venous insufficiency Venous ulceration Post-thrombotic syndrome Intravenous drug use
Infection	Cellulitis/erysipelas Lymphadenitis Tuberculosis Filariasis
Inflammation	Rheumatoid arthritis Dermatitis Psoriasis Sarcoidosis Dermatosis with epidermal involvement
Endocrine disease	Pretibial myxoedema
Immobility and dependency	Dependency oedema Paralysis
Facititious	Self-harm

childhood and rapidly spreads proximally. The condition is prevented and its progression is slowed by the wearing of shoes.

Bacterial infection

Lymphangitis and lymphadenitis can cause lymphatic destruction that predisposes to lymphoedema complicated by further acute inflammatory episodes. Interestingly, in such patients, lymphangiography has revealed abnormalities in the contralateral, unaffected limb, suggesting an underlying, possibly inherited, susceptibility. Lymphatic and lymph node destruction by tuberculosis is also a well-recognised cause of lymphoedema, especially in developing countries.

Malignancy and its treatment

Treatment (surgery, radiotherapy) for breast carcinoma is the most common cause of lymphoedema in developed countries, but is decreasing in incidence as surgery becomes more conservative (see Chapter 53). Lymphoma may present with lymphoedema, as may malignancy of the pelvic organs and external genitalia. Kaposi's sarcoma developing in the course of human immunodeficiency virus (HIV)-related illness may cause lymphatic obstruction and is a growing cause of lymphoedema in certain parts of the world.

Figure 58.8 Elephantiasis due to filariasis.

Trauma

It is not unusual for patients to develop chronic localised or generalised swelling following trauma. The aetiology is often multifactorial and includes disuse, venous thrombosis and lymphatic injury or destruction. Degloving injuries and burns are particularly likely to disrupt dermal lymphatics. Tenosynovitis can also be associated with localised subcutaneous lymphoedema, which can be a cause of troublesome persistent swelling following ankle and wrist 'sprains' and repetitive strain injury.

Lymphoedema and chronic venous insufficiency

It is important to appreciate the relationship between lymphoedema and CVI as both conditions are relatively common and so often coexist in the same patient, and it can be difficult to unravel which components of the patient's symptom complex are caused by each. There is no doubt that superficial venous thrombophlebitis (SVT) and DVT can both lead to lymphatic destruction and secondary lymphoedema, especially if recurrent. Lymphoedema is an important contributor to the swelling of the postphlebotic syndrome. It has also been suggested that lymphoedema can predispose to DVT, and possible SVT, through immobility and acute inflammatory episodes. Certainly, tests of venous function (duplex ultrasonography, plethysmography) are frequently abnormal in patients with lymphoedema.

It is not uncommon to see patients (usually women) with lymphoedema in whom a duplex ultrasound scan has revealed superficial reflux (such reflux is present subclinically in up to one-third of the adult population). Although isolated, superficial venous reflux rarely, if ever, leads to limb swelling; such patients are frequently misdiagnosed as having venous disease rather than lymphoedema, and are subjected mistakenly to varicose vein surgery. Not only will such surgery invariably fail to relieve the swelling, it will usually make it worse as saphenofemoral and saphenopopliteal ligation, together with saphenous stripping, will compromise still further drainage through the subcutaneous lymph bundles (which follow the major superficial veins) and draining inguinal and popliteal lymph nodes.

Miscellaneous conditions

Rheumatoid and psoriatic arthritis (chronic inflammation and lymph node fibrosis), contact dermatitis, snake and insect bites, and retroperitoneal fibrosis are all rare but well-documented causes of lymphoedema. Pretibial myxoedema is due to the obliteration of initial lymphatics by mucin.

Conditions mimicking lymphoedema

Factitious lymphoedema

This is caused by application of a tourniquet (a 'rut' and sharp cut-off is seen on examination) or 'hysterical' disuse in patients with psychological and psychiatric problems.

Immobility

Generalised or localised immobility of any cause leads to chronic limb swelling that can be misdiagnosed as lymphoedema, for example the elderly person who spends all day (and sometimes all night) sitting in a chair (armchair legs), the hemiplegic stroke patient and the young patient with multiple sclerosis.

Lipoedema

This presents almost exclusively in women and comprises bilateral, usually symmetrical, enlargement of the legs and, sometimes, the lower half of the body because of the abnormal deposition of fat. It may or may not be associated with generalised obesity. There are a number of features that help to differentiate the condition from lymphoedema but, of course, lipoedema may coexist with other causes of limb swelling. It has been proposed that lipoedema results from, or at least is associated with, fatty obliteration of lymphatics and lymph nodes (Summary box 58.5).

INVESTIGATION OF LYMPHOEDEMA

Are investigations necessary?

It is usually possible to diagnose and manage lymphoedema purely on the basis of history and examination, especially when the swelling is mild and there are no apparent complicating features. In patients with severe, atypical and multifactorial swelling, investigations may help confirm the diagnosis, inform management and provide prognostic information.

'Routine' tests

These include a full blood count, urea and electrolytes, creati-

Summary box 58.5**Features of lipoedema that help differentiate it from lymphoedema**

- Occurs almost exclusively in women
- Onset nearly always coincides with puberty
- Nearly always bilateral and symmetrical
- Involvement of trunk
- The feet are not involved, leading to an inverse shouldering effect at the malleoli
- No pitting
- No response to elevation or compression
- No skin changes of lymphoedema (negative Stemmer's sign)
- MRI shows subcutaneous fat but no fluid accumulation

nine, liver function tests, thyroid function tests, plasma total protein and albumin, fasting glucose, C-reactive protein, urine dipstick including observation for chyluria, blood smear for microfilariae, chest radiograph and ultrasound.

Lymphangiography

Direct lymphangiography involves the injection of contrast medium into a peripheral lymphatic vessel and subsequent radiographic visualisation of the vessels and nodes. It remains the 'gold standard' for showing structural abnormalities of larger lymphatics and nodes (Figure 58.9). However, it can be technically difficult, it is unpleasant for the patient, it may cause further lymphatic injury and, largely, it has become obsolete as a routine method of investigation. Few centres now perform this technique and those that do generally reserve it for preoperative evaluation of the rare patient with megalymphatics who is being considered for bypass or fistula ligation. Indirect lymphangiography involves the intradermal injection of water-soluble, non-

ionic contrast into a web space, from where it is taken up by lymphatics and then followed radiographically. It will show distal lymphatics but not normally proximal lymphatics and nodes.

Isotope lymphoscintigraphy

This has largely replaced lymphangiography as the primary diagnostic technique in cases of clinical uncertainty. Radioactive technetium-labelled protein or colloid particles are injected into an interdigital web space and specifically taken up by lymphatics, and serial radiographs are taken with a gamma camera. The technique provides a qualitative measure of lymphatic function rather than quantitative function or anatomical detail. Quantitative lymphoscintigraphy is performed using a dynamic (exercise) component in addition to the static test and provides information on lymphatic transport.

Computed tomography

A single, axial computed tomography (CT) slice through the midcalf has been proposed as a useful diagnostic test for lymphoedema (coarse, non-enhancing, reticular 'honeycomb' pattern in an enlarged subcutaneous compartment), venous oedema (increased volume of the muscular compartment) and lipoedema (increased subcutaneous fat). CT can also be used to exclude pelvic or abdominal mass lesions.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) can provide clear images of lymphatic channels and lymph nodes, and can be useful in the assessment of patients with lymphatic hyperplasia. MRI can also distinguish venous and lymphatic causes of a swollen limb, and detect tumours that may be causing lymphatic obstruction.

Ultrasound

Ultrasound can provide useful information about venous function including DVT and venous abnormalities.

	Normal	Congenital hyperplasia	Distal obliteration (hypo/aplasia)	Proximal obliteration (hypo/aplasia) with distal hyperplasia	Proximal obliteration (hypo/aplasia) with distal obliteration
Thoracic duct					
nodes					
Para-aortic					
Iliac					
Femoral					

Figure 58.9 Lymphangiographic patterns of primary lymphoedema.

Pathological examination

In cases in which malignancy is suspected, samples of lymph nodes may be obtained by fine-needle aspiration, needle core biopsy or surgical excision. Skin biopsy will confirm the diagnosis of lymphangiosarcoma.

Limb volume measurement

While not helpful in the diagnosis of lymphoedema, limb volume measurement is a useful tool to determine severity of lymphoedema, guide management and assess response to treatment. Limb volume is typically measured at diagnosis, following intensive treatment and at follow up. In unilateral limb swelling the affected side can be compared to the contralateral unaffected limb. In bilateral swelling the volume of both limbs is tracked with time. Measurements are recorded in millilitres or expressed as a percentage of the normal limb. Water plethysmography (water displacement) is the 'gold standard' method but is limited by practicalities of measurement and hygiene issues. Other options include circumferential limb measurements and perometry (infrared light beams measure the outline of the limb to calculate volume).

MANAGEMENT OF LYMPHOEDEMA

Overview

The evaluation of the lymphoedema patient needs to be 'holistic' and their care delivered by a multiprofessional team comprising physical therapists, nurses, orthotists, physicians (dermatologists, oncologists, palliative care specialists), surgeons and social service professionals. Although surgery itself has a very small role, surgeons (especially those with breast and vascular interests) are frequently asked to oversee the management of these patients. Early diagnosis and institution of management are essential because at that stage relatively simple measures can be highly effective and will prevent the development of disabling late-stage disease, which is extremely difficult to treat. There is often a latent period of several years between the precipitating event and the onset of lymphoedema. The identification, education and treatment of such 'at-risk' patients can slow down, even prevent, the onset of disease. In patients with established lymphoedema, the three goals of treatment are to relieve pain, reduce swelling and prevent the development of complications (Summary box 58.6).

Relief of pain

On initial presentation, 50 per cent of patients with lymphoedema complain of significant pain. The pain is usually multifactorial and its severity and underlying cause(s) will vary depending on the aetiology of the lymphoedema. For example, following treatment for breast cancer, pain may arise from the swelling itself (radiation and surgery induced); nerve (brachial plexus and intercostobrachial nerve), bone (secondary deposits, radiation necrosis) and joint (arthritis, bursitis, capsulitis) disease; and recurrent disease. Treatment involves the considered use of non-opioid and opioid analgesics, corticosteroids, tricyclic antidepressants, muscle relaxants, anti-epileptics, nerve blocks, physiotherapy and adjuvant anticancer therapies (chemo-, radio- and hormonal therapy), as well as measures to reduce swelling if possible. In patients with non-cancer-related lymphoedema, the best way to reduce pain is to control swelling and prevent the

Summary box 58.6

Initial evaluation of the patient with lymphoedema

- History (age of onset, location, progression, exacerbating and relieving features)
- Past medical history including cancer history
- Family history
- Obesity (diet, height and weight, body mass index)
- Complications (venous, arterial, skin, joint, neurological, malignant)
- Assessment of physical, emotional and psychosocial symptoms
- Social circumstances (mobility, housing, education, work)
- Special needs (footwear, clothing, compression garments, pneumatic devices, mobility aids)
- Previous and current treatment
- Pain control
- Compliance with therapy and ability to self-care

development of complications. Whatever the cause, pain is a somatopsychic experience that is affected by mood and morale. These issues are important in patients with both cancer-related lymphoedema, who are concerned about recurrent disease, and non-cancer-related disease, who often have poor self-esteem and problems with body image and perception.

Control of swelling

Physical therapy for lymphoedema comprising bed rest, elevation, bandaging, compression garments, massage and exercises was first described at the end of the nineteenth century, and through the twentieth century various eponymous schools developed. Although there is little doubt that physical therapy can be highly effective in reducing swelling, its general acceptance and practice has been hampered by a lack of proper research and confusing terminology. The current preferred term is decongestive lymphoedema therapy (DLT), which comprises two phases. The first is a short intensive period of therapist-led care and the second is a maintenance phase in which the patient uses a self-care regimen with occasional professional intervention. The intensive phase comprises skin care, manual lymphatic drainage (MLD) and multi-layer lymphoedema bandaging (MLLB), and exercises. The length of intensive treatment will depend upon the disease severity, the degree of patient compliance and the willingness and ability of the patient to take more responsibility for the maintenance phase. However, weeks rather than months should be the goal.

Skin care

The patient must be carefully educated in the principles and practice of skin care. The patient should inspect the affected skin daily, with special attention paid to skinfolds, where maceration may occur. The limb should be washed daily; the use of bath oil, e.g. Balneum, is recommended as a moisturiser and the limb must be carefully dried afterwards. A hair drier on low heat is more effective and hygienic, and less traumatic, than a towel. If the skin is in good condition daily application of a bland emollient, e.g. aqueous cream, is recommended to keep the skin hydrated. If the skin is dry and flaky then a bland ointment, e.g. 50:50 white soft paraffin/liquid paraffin (WSP/LP), should be used twice daily and, if there is marked hyperkeratosis, a keratolytic agent, such as 5 per cent salicylic acid, should be added. Many

commercially available soaps, creams and lotions contain sensitizers, e.g. lanolin in E45 cream, and are best avoided as patients with lymphoedema are highly susceptible to contact dermatitis (eczema). Apart from causing intense discomfort, eczema acts as an entry point for infection. Management comprises avoidance of the allergen (patch testing may be required) and topical corticosteroids. Fungal infections are common, difficult to eradicate and predispose to acute inflammatory episodes. Chronic application of antifungal creams leads to maceration and it is better to use powders in shoes and socks. Ointment containing 3 per cent benzoic acid helps prevent athlete's foot and can be used safely over long periods. Painting at-risk areas with an antiseptic agent such as eosin may be helpful. Lymphorrhoea is uncommon but extremely troublesome. Management comprises emollients, elevation, compression and sometimes cautery under anaesthetic (Summary box 58.7).

Summary box 58.7

Skin care

- Protect hands when washing up or gardening; wear a thimble when sewing
- Never walk barefoot and wear protective footwear outside
- Use an electric razor to depilate
- Never let the skin become macerated
- Treat cuts and grazes promptly (wash, dry, apply antiseptic and a plaster)
- Use insect repellent sprays and treat bites promptly with antiseptics and antihistamines
- Seek medical attention as soon as the limb becomes hot, painful or more swollen
- Do not allow blood to be taken from, or injections to be given into, an affected arm (and avoid blood pressure measurement)
- Protect the affected skin from sun (shade, high-factor sun block)
- Consider taking antibiotics if going on holiday

Apart from lymphangiosarcoma, acute inflammatory episodes are probably the most serious complications of lymphoedema and frequently lead to emergency hospital admission. About 25 per cent of primary and 5 per cent of secondary lymphoedema patients are affected. Acute inflammatory episodes start rapidly, often without warning or a precipitating event, with tingling, pain and redness of the limb. Patients feel 'viral' and severe attacks can lead to the rapid onset of fever, rigors, headache, vomiting and delirium. Patients who have suffered previous attacks can usually predict the onset and many learn to carry antibiotics with them and self-medicate at the first hint of trouble. This may stave off a full-blown attack and prevent the further lymphatic injury that each acute inflammatory episode causes. It is rarely possible to isolate a responsible bacterium but the majority are presumed to be caused by group A β -haemolytic streptococci and/or staphylococci. The diagnosis is usually obvious but dermatitis, thrombophlebitis and DVT are in the differential diagnosis. Oral amoxycillin is the treatment of choice with erythromycin or clarithromycin in those with penicillin allergy. Flucloxacillin should be added for those with evidence of *S. aureus* infection (folliculitis, crusted dermatitis). Oral clindamycin is a second line agent for those with failure to respond to initial therapy. Hospital admission is required for

patients with: signs of septicaemia; continuing or deteriorating systemic signs after 48 hours of antibiotic treatment; unresolving or deteriorating local signs despite trials of first- and second-line antibiotics. Intravenous amoxycillin or benzyl penicillin with clindamycin in penicillin-allergic patients or as second-line therapy is most commonly recommended. Bed rest will reduce lymphatic drainage and the spread of infection, elevation will reduce the oedema and heparin prophylaxis will reduce the risk of DVT. Analgesia is often required but non-steroidal anti-inflammatories (NSAIDs) should be avoided as they have been associated with increased complications including necrotising fasciitis. Any lymphatic massage should be ceased in the presence of active infection. Amoxycillin can be taken by patients who self-medicate. The use of long-term prophylactic antibiotics is not evidence based, but penicillin V 500 mg daily is probably reasonable in patients who suffer two or more attacks per year. However, the benefits of scrupulous compliance with physical therapy and skin care cannot be underestimated.

Manual lymphatic drainage

Several different techniques of MLD have been described and the details are beyond the scope of this chapter. However, they all aim to evacuate fluid and protein from the interstitial space and stimulate lymphangion contraction with decongestion of impaired lymphatic pathways and development of collateral routes. The therapist should perform MLD daily; they should also train the patient (and/or carer) to perform a simpler, modified form of massage termed simple lymphatic drainage (SLD). In the intensive phase, SLD supplements MLD and, once the maintenance phase is entered, SLD will carry on as daily massage.

Multilayer lymphoedema bandaging and compression garments

Elastic bandages provide compression, produce a sustained high resting pressure and 'follow in' as limb swelling reduces. However, the sub-bandage pressure does not alter greatly in response to changes in limb circumference consequent upon muscular activity and posture. By contrast, short-stretch bandages exert support through the production of a semi-rigid casing where the resting pressure is low but changes quite markedly in response to movement and posture. This pressure variation produces a massaging effect within the limb and stimulates lymph flow. Whether the aim is to provide support or compression, the pressure exerted must be graduated (100 per cent ankle/foot, 70 per cent knee, 50 per cent mid-thigh, 40 per cent groin).

Non-invasive assessment of the ankle-brachial pressure index (ABPI) using a hand-held Doppler ultrasound device is usually necessary prior to commencing any form of compression therapy, as it is rarely possible to feel pulses in the lymphoedematous limb. Standard MLLB and compression is used in patients with ABPI ≥ 0.8 and modified techniques with lower pressures in those with moderate arterial disease (ABPI 0.5–0.8). MLLB is contraindicated in severe arterial insufficiency (ABPI < 0.5), uncontrolled heart failure and severe peripheral neuropathy.

It is generally believed that non-elastic MLLB is preferable (and arguably safer) in patients with severe swelling during the intensive phase of DLT (Summary box 58.8), whereas compression (hosiery, sleeves) is preferable in milder cases and during the maintenance phase. MLLB is highly skilled and to be effective and safe it needs to be applied by a specially trained therapist. It is also extremely labour intensive, needing to be changed daily.

Summary box 58.8**Effects of MLLB**

- Reduces oedema
- Restores shape to the affected area
- Reduces skin changes (hyperkeratosis, papillomatosis)
- Eliminates lymphorrhoea
- Supports inelastic skin
- Softens subcutaneous tissues

Compression garments form the mainstay of management in most clinics. The control of lymphoedema requires higher pressures (30–40 mmHg arm, 40–60 mmHg leg) than are typically used to treat CVI. These may be reduced to 15–25 mmHg in those with moderate arterial insufficiency (Figure 58.10). Confusingly, the British (classes I: 14–17 mmHg; II: 18–24 mmHg; III: 25–35 mmHg) and international (USA) (classes I: 20–30 mmHg; II: 30–40 mmHg; III: 40–50 mmHg; IV: 50–60 mmHg) standards are different. The patient should put the stocking on first thing in the morning before rising. It can be difficult to persuade patients to comply. Putting lymphoedema-grade stockings on and off is difficult and many patients find them intolerably uncomfortable, especially in warm climates. Furthermore, although intellectually they understand the benefits, emotionally they may find wearing them presents a greater body image problem than the swelling itself.

Enthusiasm for pneumatic compression devices has waxed and waned. Unless the device being used allows the sequential inflation of multiple chambers up to >50 mmHg, it will probably be ineffective for lymphoedema. The benefits to the patient are maximised and complications are minimised if these devices are used under the direction of a physical therapist as part of an overall package of care.

Exercise

Lymph formation is directly proportional to arterial inflow and 40 per cent of lymph is formed within skeletal muscle. Vigorous exercise, especially if it is anaerobic and isometric, will tend to exacerbate lymphoedema and patients should be advised to avoid prolonged static activities, for example carrying heavy shopping bags or prolonged standing. In contrast, slow, rhythmic isotonic movements (e.g. swimming) and massage will increase venous and lymphatic return through the production of movement between skin and underlying tissues (essential to the filling of initial lymphatics) and augmentation of the muscle pumps. Exercise also helps to maintain joint mobility. Patients who are unable to move their limbs benefit from passive exercises. When at rest, the lymphoedematous limb should be positioned with the foot/hand above the level of the heart. A pillow under the mattress or blocks under the bottom of the bed will encourage the swelling to go down overnight.

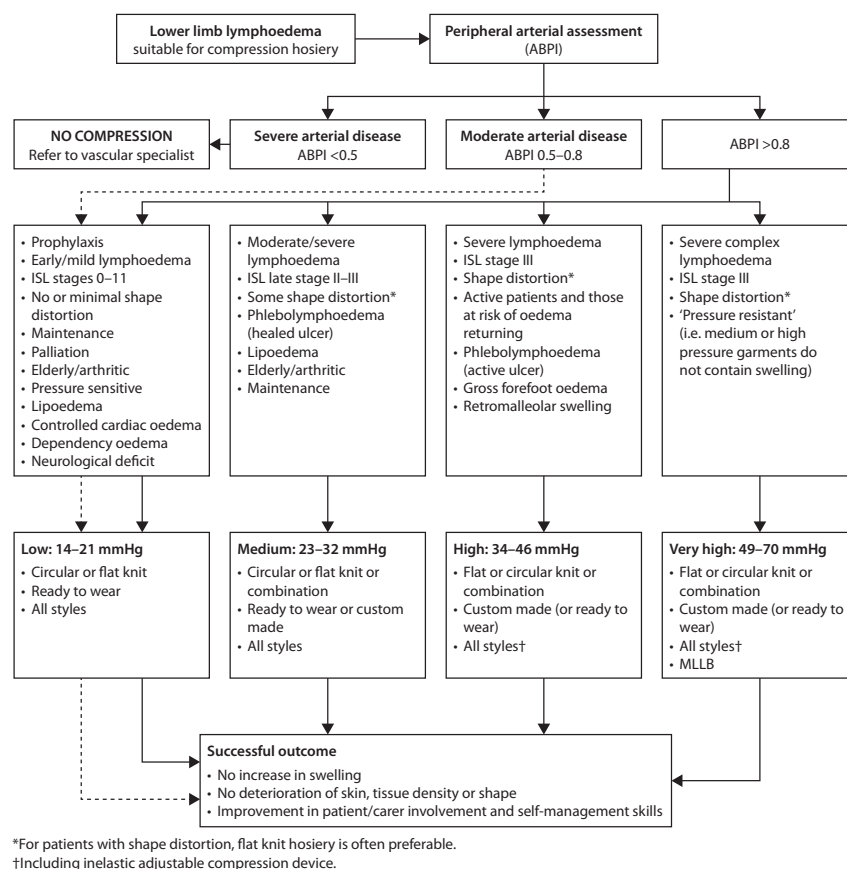

Figure 58.10 Compression garments for lower limb oedema and lymphovenous oedema. Reproduced with permission from: Lymphoedema Framework. *Best Practice Management of Lymphoedema*. International Consensus. London: MEP Ltd, 2006. © MEP Ltd 2006.

Drugs

There are considerable, and scientifically inexplicable, differences in the use of specific drugs for venous disease and lymphoedema between different countries. The benzopyrones are a group of several thousand naturally occurring substances, of which the flavonoids have received the most attention. Enthusiasts will argue that a number of clinical trials have shown benefit from these compounds, which are purported to reduce capillary permeability, improve microcirculatory perfusion, stimulate interstitial macrophage proteolysis, reduce erythrocyte and platelet aggregation, scavenge free radicals and exert an anti-inflammatory effect. Detractors will argue that the trials are small and poorly controlled with short follow up and 'soft' end points, and that any benefits observed can be explained by a placebo effect. In the UK, oxerutins (Paroven®) are the only such drugs licensed for venous disease and none has a license for lymphoedema. Diuretics are of no value in pure lymphoedema. Their chronic use is associated with side effects, including electrolyte disturbance, and should be avoided.

With increasing understanding of lymphangiogenesis pathways there is hope that specific pharmacological targets or gene therapy may become available in the future but this remains in the very early stages at present.

Surgery

Only a small minority of patients with lymphoedema benefit from surgery. Operations fall into three categories: bypass procedures, liposuction and reduction procedures.

Bypass procedures

The rare patient with proximal ilioinguinal lymphatic obstruction and normal distal lymphatic channels might benefit, at least in theory, from lymphatic bypass. A number of methods have been described including the omental pedicle, the skin bridge (Gillies), anastomosing lymph nodes to veins (Neibulowitz) and the ileal mucosal patch (Kinmonth). More recently, direct lymphaticovenular anastomosis (LVA) has been carried out on vessels of 0.3–0.8 mm diameter using supermicrosurgical techniques. The procedures are technically demanding and not without morbidity. They are more often attempted in the upper limb following lymph node resection or radiotherapy for breast cancer. The outcomes are best in patients with earlier stages of lymphoedema for whom the majority can be controlled with best medical therapy alone. In those with later stage disease who have failed conservative management, the outcomes of LVA have generally been disappointing.

Liposuction

Liposuction has been used in the treatment of chronic lymphoedema. It is usually reserved for patients who have progressed to non-pitting oedema. Case series reported thus far have shown promising results with more than 100 per cent reduction in limb oedema volume which can be maintained by ongoing use

of compression hosiery for at least one year. While liposuction appears to be safe, results of long-term efficacy and effects on the incidence of future lymphoedema complications (e.g. infection) are awaited.

Limb reduction procedures

These are indicated when a limb is so swollen that it interferes with mobility and livelihood. These operations are not 'cosmetic' in the sense that they do not create a normally shaped leg and are usually associated with significant scarring. Four operations have been described.

Sistrunk

A wedge of skin and subcutaneous tissue is excised and the wound closed primarily. This is most commonly carried out to reduce the girth of the thigh.

Homans

First, skin flaps are elevated, and then subcutaneous tissue is excised from beneath the flaps, which are then trimmed to size to accommodate the reduced girth of the limb and closed primarily. This is the most satisfactory operation for the calf (Figure 58.11). The main complication is skin flap necrosis. There must be at least six months between operations on the medial and lateral sides of the limb and the flaps must not pass the midline. This procedure has also been used on the upper limb, but is contraindicated in the presence of venous obstruction or active malignancy.

Figure 58.11 Homans' procedure involves raising skin flaps to allow the excision of a wedge of skin and a larger volume of subcutaneous tissue down to the deep fascia. Surgery to the medial and lateral aspects of the leg must be separated by at least six months to avoid skin flap necrosis.

Sir Harold Delf Gilles, 1882–1960, plastic surgeon, St Bartholomew's Hospital, London, UK. Born in New Zealand, widely considered the 'Father of Plastic Surgery', started his craft to better the lives of the victims of the First World War. Later he became a pioneer in 'gender reassignment (sex-change) surgery'. He was joined in private practice by his cousin, the other world famous plastic surgeon, Sir Archibald McIndoe. He excelled in most sports – cricket, rowing, golf, and was an accomplished painter.

John Bernard Kinmonth, 1916–1982, surgeon, St Thomas's Hospital, London, UK.

Walter Ellis Sistrunk, 1880–1933, Professor of Clinical Surgery, Baylor University College of Medicine, Dallas, TX, USA.

Frederick Thompson, 1910–1975, plastic surgeon, The Middlesex Hospital, London, UK.

Major-General Sir Richard Havelock Charles, 1887–1934, a surgeon in The Indian Medical Service.

Thompson

This is a modification of the Homans' procedure aimed to create new lymphatic connections between the superficial and deep systems. One skin flap is denuded (shaved of epidermis), sutured to the deep fascia and buried beneath the second skin flap (the so-called 'buried dermal flap') (Figure 58.12). This procedure has become less popular as pilonidal sinus formation is common. The cosmetic result is no better than that obtained with the Homans' procedure and there is no evidence that the buried flap establishes any new lymphatic connections.

Figure 58.12 A cross-sectional representation of Thompson's reduction operation; red arrows illustrate the buried dermal flap sutured to deep fascia.

Charles

This operation was initially designed for filariasis and involved excision of all of the skin and subcutaneous tissues down to the deep fascia, with coverage using split-skin grafts (Figure 58.13). This leaves a very unsatisfactory cosmetic result and graft failure is not uncommon. However, it does enable the surgeon to reduce greatly the girth of a massively swollen limb.

Chylous ascites and chylothorax

These are associated with megalymphatics. The diagnosis may be obvious if accompanied by lymphoedema and lymphangioma. However, some patients develop chylous ascites and/or chylothorax in isolation, in which case the diagnosis can be confirmed by aspiration and the identification of chylomicrons in the aspirate. Cytology for malignant cells should also be carried out. A CT scan may show enlarged lymph nodes and CT with guided biopsy, laparoscopy or even laparotomy and biopsy may be necessary to exclude lymphoma or other malignancy. Lymphangiography may indicate the site of a lymphatic fistula that can be surgically ligated. Even if no localised lesion is identified, it may be possible to control leakage at laparotomy or even remove a segment of affected bowel. If the problem is

Figure 58.13 The Charles procedure involves circumferential excision of lymphoedematous tissue down to and including the deep fascia followed by split-skin grafting. This procedure gives a very poor cosmetic result but does allow the surgeon to remove very large amounts of tissue and is particularly useful in patients with severe skin changes.

too diffuse to be corrected surgically, a peritoneal venous shunt may be inserted, although occlusion and infection are important complications. Medical treatment comprising the avoidance of fat in the diet and the prescription of medium-chain triglycerides (which are absorbed directly into the blood rather than via the lymphatics) may reduce swelling. Chylothorax is best treated by pleurodesis, but this may lead to death from lymph-logged lungs as the excess lymph has nowhere to drain.

Chyluria

Filariasis is the most common cause, with chyluria occurring in 1–2 per cent of cases 10–20 years after initial infestation. It usually presents as painless passage of milky white urine, particularly after a fatty meal. The chyle may clot, leading to renal colic, and hypoproteinaemia may result. Chyluria may also be caused by ascariasis, malaria, tumour and tuberculosis. Intravenous urography and/or lymphangiography will often demonstrate the lymphourinary fistula. Treatment includes a low-fat and high-protein diet, increased oral fluids to prevent clot colic, and laparotomy and ligation of the dilated lymphatics. Attempts have also been made to sclerose the lymphatics either directly or via instrumentation of the bladder, ureter and renal pelvis.

History and examination of the abdomen

LEARNING OBJECTIVES

To understand:

- The pathway for clinical diagnosis of a patient presenting with an abdominal complaint
- The importance of recognising the organ or system responsible for the clinical features
- The pathophysiological basis of common abdominal symptoms and signs

To identify:

- Leading questions based on the organ or system affected and reach the most likely differential diagnosis
- The relevant physical signs and come to an appropriate clinical diagnosis

INTRODUCTION

Abdominal symptoms are possibly the most frequent of all symptoms encountered in surgical practice. Most symptoms arise from intra-abdominal organs or systems while some may originate extraabdominally and are then referred to the abdomen.

GATHERING INFORMATION

The first step is to obtain a history from the patient. But even before that, initial observations provide clues to the direction which the history should take; general appearance, gait, position in bed, facial expression, tone of the speech, all provide useful hints. The patient will be frightened and may well be in severe pain; therefore, the clinician should try to comfort the patient and gain their confidence, especially in cases of abdominal pain presenting as an emergency.

Obtaining a history

During the initial part of the interview with the patient, it is best to encourage the patient to explain their problem without interruption. After that, leading questions are used to fill any gaps left in the patient's history.

Presenting complaint

One should start with an open question inviting the patient to explain their reason for seeking medical advice.

Duration of the presenting complaint

The duration of symptoms will profoundly affect the differential diagnosis. For example, abdominal pain, which lasts for a few hours, may be ureteric colic whereas long-standing abdominal pain may be more suggestive of peptic ulceration.

History of the presenting complaint

Once the patient has finished explaining their problem, leading questions should be used to support or exclude the likely diagnoses. One way to do this is to enquire exactly when the patient last felt well and then ask about all that has happened since. At this stage it should be possible to identify a likely organ or system responsible for the patient's symptoms and come to a differential diagnosis. For example, a patient who presents with episodic loose stools, left-sided abdominal pain and sense of incomplete evacuation of bowel is likely to have pathology in the colon or rectum. In this case the relevant questions would be whether there was blood and mucus in the stools, and if there were constitutional symptoms suggestive of anaemia, malignancy and a family history of colon cancer.

Some patients may volunteer information that at first may not sound relevant but must be heeded. This is particularly important in the Asian subcontinent where people do resort to alternative medicines, which may have their own side effects.

Past history

The past history is important as it may have a bearing on the diagnosis and management. For example, control of diabetes will be difficult in the presence of intra-abdominal suppuration until the pus is drained. Some symptoms and signs may be due to comorbid conditions. A patient with abdominal pain due to gallstones may also have bilateral ankle oedema due to congestive cardiac failure. A tendency towards depression and anxiety may have an effect on the outcome of surgery.

Drug history and allergies

Some drugs will have an effect on the symptoms and signs or will have to be discontinued prior to surgery if they are not to cause complications. For example, a patient on a beta-blocker with abdominal bleeding will not have tachycardia.

proportionate to the blood loss. A patient on long-term steroids will need intravenous steroids to prevent an adrenal crisis in the perioperative period.

Social history

The use of alcohol and illicit drugs, smoking and occupation are important. Family background will give an idea as to the possible family support that can be expected after discharge from hospital.

Family history

Genetic disorders including adverse reactions to anaesthetics and medications need to be recorded. Any family history of cancer, particularly in a first-degree relative, is especially important.

Review of the systems

A system review should highlight any comorbid disease, such as cardiac, vascular, respiratory or endocrine problems (Summary box 59.1).

Summary box 59.1

Principles of history-taking

- Identify the reason for consultation
- Identify the duration and evolution of the problem
- Recognise the most likely organ or system affected
- Recall the relevant leading questions
- Select the most likely pathology from a list of differential diagnoses

CLINICAL PRESENTATION OF ABDOMINAL PROBLEMS

Pain, dyspepsia and alteration of bowel habit are the three common clinical presentations of pathology in the abdomen. However, it is important to be vigilant about insidious presentations of malignancies. Classic examples are right colon cancers presenting with symptoms of anaemia, malignant infiltrations of the liver with weight loss, gastric cancers with loss of appetite, abdominal lymphomas with weight loss and fever, ovarian cancers with abdominal distension, adrenal cancers with weight gain, and malignant obstructions of the extrahepatic biliary tree presenting with jaundice (Summary box 59.2).

Summary box 59.2

Sources of abdominal symptoms

- Abdominal pain, dyspepsia and alteration of bowel habit are the three common clinical presentations of abdominal pathology
- Occult malignancies may have atypical presentations

Abdominal pain

Pain is the most common of all abdominal symptoms. This may be due to inflammatory, infective or obstructive pathology. These can arise from abdominal viscera or be referred from a

site outside the abdomen, such as the lungs as in pneumonia or the heart as in angina. Sometimes there may be abdominal pain for which no organic cause can be found, a situation labelled 'functional abdominal pain' for want of a better term. Common examples are dyspepsia or irritable bowel syndrome (IBS).

Acute medical conditions

Acute abdominal pain from medical conditions such as diabetic ketoacidosis and porphyrias may present as apparent surgical emergencies. It is also important to be vigilant about the atypical presentations of life-threatening abdominal problems and hidden malignancies. For example, an elderly man presenting with vague abdominal pain combined with an episode of fainting may have a leaking abdominal aortic aneurysm. Young alcoholics presenting to the Accident and Emergency department with abdominal pain and a recent history of trauma may be developing traumatic acute pancreatitis or a traumatic subcapsular haematoma of the spleen. The elderly patient presenting with a clinical picture of acute appendicitis and anaemia should arouse suspicion of a concomitant caecal cancer as a cause of obstructive appendicitis.

Abdominal pain and dyspepsia

The word dyspepsia is used to describe a multitude of symptoms, such as upper abdominal pain, abdominal distension, discomfort, early satiety, nausea, vomiting, heartburn, acid regurgitation and water brash; all these symptoms are referable to the upper gastrointestinal tract. They are called 'organic dyspepsias', the most common cause of which is gastro-oesophageal reflux disease. Other causes are peptic ulcer, gallstones, chronic pancreatitis and oesophagogastric cancer. However, in approximately 50 per cent of patients a definitive diagnosis cannot be made. In these cases the term 'functional dyspepsia' is used.

Abdominal pain and change of bowel habits

Alteration in bowel habit makes the colon the likely source of pathology. The onset, nature, duration, type of alteration (constipation or diarrhoea) and its relationship to abdominal pain will help to differentiate organic pathology causing obstruction or inflammation (colon cancer and inflammatory bowel disease) from functional conditions such as IBS. When patients complain of diarrhoea, they may imply different meanings – some use the term for loose stools, while others may mean frequent but normal stools. A long-standing increase in frequency of stools, with left-sided abdominal pain prior to defecation which eases after defecation, all points to IBS. However, if such symptoms are of short duration in an adult and are associated with blood and mucus in the stools with weight loss, a left colonic carcinoma is more likely. If a patient with such symptoms presents as an emergency with worsening abdominal pain and absolute constipation, then the most likely diagnosis is one of acute-on-chronic intestinal obstruction, from a stenotic left colon cancer. If the patient also has a distended abdomen and tenderness over the caecal area, then closed-loop obstruction with impending caecal rupture must be suspected and urgent surgery will be needed. However, a history of previous abdominal surgery changes the situation again; now, adhesions entrapping the small bowel is the most likely source of the symptoms. However, a small incarcerated femoral hernia could also be the cause. This can easily be missed, especially in an obese patient (Summary box 59.3).

Summary box 59.3**Classic presentations of abdominal pathology**

- Obstructive and inflammatory pathology must be excluded in patients with abdominal pain and altered bowel habit
- Closed-loop obstruction with tenderness in the right iliac fossa is indicative of imminent caecal rupture
- Caecal cancer classically presents with anaemia
- Patients who have had previous abdominal surgery may have adhesions
- Check carefully for small incarcerated hernias, particularly femoral, in obese patients

Summary box 59.4**Nerves responsible for abdominal pain**

- Abdominal wall and parietal peritoneum are supplied by the somatic nerves
- Abdominal organs and the visceral peritoneum are supplied by the autonomic nervous system
- Skin, muscles and parietal peritoneum are supplied by the iliohypogastric and ilioinguinal nerve and the lower six intercostal nerves
- Afferent pain fibres from the abdominal organs and visceral peritoneum travel with sympathetic nerves

PATHOPHYSIOLOGICAL BASIS OF COMMON ABDOMINAL SYMPTOMS AND SIGNS

The abdominal wall and parietal peritoneum are supplied by the somatic nervous system, while the abdominal organs and visceral peritoneum are innervated by the autonomic nervous system. Therefore pain will appear to change in position and nature as the underlying pathology spreads from a local intraperitoneal structure to the parietal peritoneum.

The skin and the muscles of the abdominal wall are supplied by the lateral and anterior cutaneous branches of the lower six intercostal nerves and the iliohypogastric and ilioinguinal nerve (Figure 59.1). The dermatome levels of the xiphoid process, umbilicus and pubis are T7, T10 and T12, respectively. The parietal peritoneum is supplied segmentally by the same nerves that innervate the overlying muscles. The central part of the diaphragmatic peritoneum is supplied by the phrenic nerve (C4); therefore, pain arising in this region is referred to the tip of the shoulder as it has the same segmental supply. The peripheral rim of the diaphragmatic peritoneum is supplied by the intercostal nerves. The obturator nerve is the chief nerve supply of the pelvic parietal peritoneum (Summary box 59.4).

Figure 59.1 Distribution of the anterior abdominal wall dermatomes and nerves.

Pain from the viscera is principally due to ischaemia, muscle spasm and stretching of the visceral peritoneum. Unlike somatic pain, autonomic pain is deep and poorly localised. This pain is transmitted via sympathetic fibres and so is referred to the appropriate somatic distribution of that nerve root from T1 to L2 (Figure 59.2). However, when an inflamed organ touches the parietal peritoneum, the pain becomes sharp and localises to the appropriate segmental dermatome of the abdominal wall. Pain arising from the parietal peritoneum may radiate to the back or the front along the appropriate dermatome. This referral pattern is classically seen in acute cholecystitis when an inflamed gall bladder touches the parietal peritoneum. Pain then radiates round to the back along the involved dermatome. The overlying muscle and the skin is supplied by the same nerve root, so when the patient takes a deep breath the tenderness in the right subcostal region is markedly increased, causing the patient to stop breathing; this is Murphy's sign. In children with abdominal pain, who hold their right hip in a flexed position to obtain relief from the pain, one should suspect retrocaecal appendicitis causing irritation of the psoas muscle.

Figure 59.2 Pathways for parietal and visceral pain. (From 25th Edition of Bailey and Love, courtesy of Mr Simon Paterson-Brown, Consultant Surgeon, Royal Infirmary of Edinburgh.)

The pattern of pain distribution from the various regions of the gut is most easily understood by appreciating that the gut develops with its own nerve supply. Pain arising from the foregut is felt in the epigastric region while pain from the mid-gut, which includes the small bowel, appendix and ascending colon, is referred to the periumbilical region (Summary box 59.5).

Summary box 59.5

Specific characteristics of abdominal pain

- Visceral pain arises from ischaemia, muscle spasm and stretching of the visceral peritoneum
- Autonomic pain, deep and poorly localised, is referred to the equivalent somatic distribution of that nerve root from T1 to L2
- When an inflamed organ touches the parietal peritoneum, pain is then localised to the segmental dermatome of the abdominal wall
- The pain in the parietal peritoneum may radiate to back or front along the dermatome

Obstruction

Central colicky abdominal pain is a classical presentation of small bowel obstruction. The central distribution is because of the segmental nerve supply of the mid-gut. When the peristaltic waves hit an obstruction, the contractions increase to overcome the resistance producing the colic. The pain reaches a crescendo and then disappears in minutes when the peristaltic wave passes (Figure 59.3). This is different from that of biliary colic. When the gall bladder contracts against a stone, pain is relatively insidious in onset and reaches its peak in about half an hour and then eases off. A basal pain persists between the bouts of colic (Summary box 59.6).

Rupture and perforation of organs

The urinary bladder, gall bladder and gastrointestinal tract are hollow organs containing fluid. The gastrointestinal system also contains faeces, air and a high concentration of organisms. Trauma and ischaemia may cause perforation, leak of contents and peritonitis. Air leaking from the bowel gets trapped

Figure 59.3 Time/intensity graph for the pain of obstruction. (From 25th Edition of Bailey and Love, courtesy of Mr Simon Paterson-Brown, Consultant Surgeon, Royal Infirmary of Edinburgh.)

Summary box 59.6

Colicky abdominal pain

- The pain of 'small bowel colic' comes in waves and disappears completely in minutes when the peristaltic wave ceases
- Pain of biliary colic is insidious in onset, reaches the peak in half an hour or so and does not ease off completely between spasms

between the liver and abdominal wall; hence the loss of hepatic dullness, a physical sign that supports the diagnosis of perforation of a hollow viscus. Rupture of the bowel causes sudden pain. The initial site of onset of the pain may give a clue as to the organ involved and so help with the differential diagnosis. For example, the diagnosis of a perforated peptic ulcer is supported by a past history of ulcer-type pain followed by sudden onset of upper abdominal pain. In such a patient who has peritonitis the abdominal wall will not move with respiration. The patient will have thoracic respiration with shallow breathing.

The abdomen is divided into nine areas for ease of description (Figure 59.4). These regions are demarcated by the midclavicular lines in the vertical axis and by the transpyloric and transtuberular lines in the horizontal axis. Figure 59.4 also indicates some of the common organs and pathological processes that commonly cause pain experienced in these regions.

EXAMINATION OF THE ABDOMEN

Abdominal examination must be preceded by a detailed general examination of the patient as a whole. Physical examination

Figure 59.4 Nine sites of abdominal pain: 1, right subcostal; 2, epigastrium; 3, left subcostal; 4, right flank; 5, periumbilical; 6, left flank loin; 7, right iliac fossa; 8, suprapubic/hypogastrium; 9, left iliac fossa. (From 25th Edition of Bailey and Love, courtesy of Mr Simon Paterson-Brown, Consultant Surgeon, Royal Infirmary of Edinburgh.)

should be systematic using the following sequence: inspection, palpation, percussion and auscultation (Summary box 59.7).

Summary box 59.7

Inspection of abdomen

- Kneel beside the bed with eyes level with patient's anterior abdominal wall
- Look for skin colour changes (Grey Turner and Cullen's signs)
- Look for surgical scars
- Check for lumps and distended veins and pulsation
- Watch the abdomen move with respiration
- Intra-abdominal lumps vanish or become less prominent when the patient tenses the abdominal wall by lifting the head from the bed

General examination

Observation of the patient's general condition is useful even before starting to take the history, especially in the emergency situation. If a patient resorts to the knee–elbow position to get relief from pain, it indicates that the pain is of pancreatic origin (Figure 59.5). In the outpatient clinic, a patient with loose clothing (most likely caused by significant weight loss) may well have an underlying malignant process. The differential diagnosis will include tuberculosis, Crohn's disease or chronic pancreatitis. In a patient with anaemia, a clinician should check for nodes in the supraclavicular region from gastric cancer, other nodal masses from lymphoma, as well as a caecal mass and malignant hepatomegaly when the liver will be large with hard nodules. Bilateral lower limb oedema is a significant finding, which may point to heart, liver or renal failure as well as obstruction of the veins in the pelvis (Summary box 59.8).

Figure 59.5 Classical position adopted to ease pancreatic pain (patient with chronic pancreatitis).

Summary box 59.8

Sources of physical signs in abdominal examination

- Malignancy, tuberculosis, Crohn's disease and chronic pancreatitis should be suspected in a patient who appears to have lost weight
- Occult gastrointestinal bleeding from chronic peptic ulceration and right colon cancers should be excluded in patients with anaemia
- The cause of bilateral lower limb oedema may be in the heart, liver, kidneys or in venous obstruction in the pelvis

Inspection

Scars, distension, peristalsis, masses, dilated veins, pulsations and abdominal wall swellings suggestive of hernia should all be carefully sought. In an abdominal emergency look for Grey Turner's sign – skin discoloration of flanks due to retroperitoneal haemorrhage in severe acute pancreatitis and leaking abdominal aortic aneurysm. The other cause of skin colour change is Cullen's sign – discoloration around the umbilicus from severe acute pancreatitis, ruptured ectopic pregnancy or trauma to the liver. In these situations blood tracks to the umbilicus along the ligamentum teres (Figure 59.6).

In a patient with acute abdominal pain, always check to see if the abdominal wall moves with respiration. If only the thorax moves then peritonitis should be suspected. Visible abdominal masses, mobility on respiration and peristalsis are all best observed by the clinician kneeling by the patient's bed so that the observer's eye is at the level of the patient's anterior abdominal wall. The same position is useful during palpation for abdominal masses (Figure 59.7).

Figure 59.6 Cullen's and Grey Turner's sign of skin discolouration of flanks and around umbilicus (courtesy of Mr Pradip Datta, Honorary Consultant Surgeon, Wick, Scotland).

George Grey Turner, 1877–1951, Professor of Surgery, the University of Durham (1927–1934) and at the Royal Postgraduate Medical School, Hammersmith Hospital, London, UK (1935–1946). He had the surgical club, Grey Turner Surgical Club, named after him. It is said that he dressed shabbily so that when his friends met him they used to ask him to 'mend the clock'. He had a habit of keeping his cup of tea warm by covering it with his bowler hat!

Thomas Stephen Cullen, 1868–1953, Professor of Gynaecology, the Johns Hopkins University, Baltimore, MD, USA, described the sign in ruptured ectopic pregnancy in 1916.

Figure 59.7 Eye at the level of patient's abdominal wall.

Palpation

Palpation should be performed in a systematic manner checking all nine regions of the abdomen (Figure 59.4). Palpation is started in the region furthest away from the site of pain. The examiner should observe the patient's facial expression throughout. It may help to divert the patient's attention by having a conversation. Watch their face so that you spot discomfort immediately. A relaxed patient with a pillow under the flexed knees makes the procedure easier. A gentle approach and warm hands will allay the patient's fears. Palpate superficially to identify tender areas then follow this with deep palpation. Take special care wherever tenderness is found in superficial palpation. Finally, palpation during respiration is performed to identify those structures like the liver and spleen which move with respiration.

Signs of parietal peritoneal irritation (tenderness, guarding, rebound tenderness, rigidity)

In the presence of abdominal pain, the degree of abdominal wall rigidity and involuntary guarding should be assessed. Guarding represents contraction of the abdominal wall muscles over the area of pain. This might occur 'voluntarily' when the patient wishes to avoid the pain from examination, or 'involuntarily' when the muscles go into spasm as the inflamed viscus touches the parietal peritoneum. This produces a reflex spasm of the overlying abdominal wall muscles. The presence of rebound tenderness indicates underlying peritoneal inflammation and is best examined using gentle percussion, although pain on coughing is also found when there is rebound tenderness. When the underlying peritoneal inflammation becomes generalised, the abdomen is 'board-like rigid' to palpation, and selective tenderness can no longer be elicited. This sign represents widespread involuntary guarding. The progression from tenderness, guarding, rebound tenderness are all stages in the evolution of generalised peritonitis.

Abdominal masses

A mass arising from the anterior abdominal wall will usually be mobile when the patient is relaxed. On contracting the abdominal wall muscles (ask the patient to lift their legs with the

knees extended, or by a Valsalva manoeuvre for laterally placed swellings), lumps superficial to the abdominal wall muscles will become more obvious, and those attached to the deep fascia will become less mobile. Those arising within the muscle layer will become fixed and remain unchanged in size. Lumps arising deep to the abdominal wall (i.e. within the peritoneal cavity or behind the peritoneum) will become impalpable or less prominent on tensing the anterior abdominal wall muscles.

Intraperitoneal lumps in contact with the diaphragm will move on respiration (i.e. swellings arising from liver, gall bladder, spleen, stomach, kidneys and suprarenals). Retroperitoneal masses are usually fixed and certainly do not move with respiration; an enlarged kidney is 'ballotable' and bimanually palpable. Normal aortic pulsations can be both seen and felt in a thin abdomen, but expansile pulsation is characteristic of an abdominal aortic aneurysm. This should be differentiated from transmitted pulsation of a mass sitting on the aorta (e.g. pseudocyst of the pancreas).

When 'palpating during inspiration', the examining hand is placed distal to the normal site of the organ, and is held there until the edge of the organ descends and touches the examiner's fingers (Figure 59.8). Liver, spleen, gall bladder and kidneys are best palpated during inspiration.

In the female an abdominal mass, whose lower limit cannot be made out, must be arising from the pelvis. If the mass can be moved in a transverse direction, then it is likely to be an uterine or ovarian mass (Figure 59.9). If the lower limit of an abdominal mass is palpable and it is mobile, then it will be an intra-abdominal mass; the origin of this mass will be dependent upon the site (Figure 59.10) and the pathology dependent upon the clinical features as a whole. If a mass is of recent origin overlying a laparoscopic scar, without any signs of inflammation, consider a secondary metastasis of an intra-abdominal malignancy (Figure 59.11).

Spleen

In a healthy patient the spleen is not palpable. The enlarged spleen descends downwards, forwards and medially. Palpation

Figure 59.8 Palpation during inspiration. Examining hand is placed distal to the intended site of the organ until the edge of the organ descends and hits the hand.

Figure 59.9 Large suprapubic mass. Patient referred with diagnosis of ovarian tumour with liver metastasis; investigations showed fibroid uterus with multiple haemangiomas in the liver.

Figure 59.10 Mass in the right iliac fossa: carcinoma caecum (courtesy of Mr Pradip Datta, Honorary Consultant Surgeon, Wick, Scotland).

for an enlarged spleen is best performed in a supine patient. The examining hand should start in the right lower abdomen, with the tips of the fingers pointing upwards and pressed inwards. The patient is then asked to take a deep breath, and if the spleen is enlarged the lower edge with the characteristic notch will touch the fingers. If it is not palpable, then the hand is gradually moved upwards in the direction of the position of the edge of the normal-sized spleen with each breath. If the spleen is still not palpable, the patient is moved to the right lateral position and the examination repeated.

Liver

In a supine patient, the hand is placed in line with the potential enlarged liver edge lateral to the rectus muscle (Figure 59.8). The patient is then asked to take a deep breath. If the liver is enlarged sufficiently below the costal margin, then surface irregularities can also be felt.

Percussion

Percussion helps to distinguish distension due to bowel gas from free fluid in the abdomen and solid masses. Percussion is most sensitive when the examiner moves from resonant parts of the abdomen to dull ones. In patients with free fluid in the perito-

neal cavity, percussion from the centre to the periphery reveals dullness of flanks. Shifting dullness is elicited if the patient is re-examined lying on their side. The margin of dullness is then found to shift when the patient has moved.

Percussion is a very sensitive and refined method of testing for rebound tenderness. If the patient winces with pain on abdominal percussion it denotes underlying peritonitis.

Auscultation

High-pitched bowel sounds are heard during early stages of mechanical intestinal obstruction. Aortic and iliac bruits are heard when blood flows through a stenosis. A succussion splash is a sound like 'shaking a half-filled bottle with water' and is found most often in patients with gastric stasis due to gastric outlet obstruction. In generalised peritonitis, bowel sounds will not be heard or be very few and far between.

Inspection of hernial sites, examination of genitalia, inspection of anal region and digital rectal examination

Abdominal examination is not complete until all external hernial sites and the anal area have been carefully inspected, the genitalia examined and a digital rectal examination performed. A vaginal examination will also be needed in females. The spine and renal angles should be examined.

VALUE OF OBSERVATION AND REVIEW

In the case of acute abdominal pain, there will be a group of patients in whom, after full clinical assessment, the surgeon is still uncertain about the need for an urgent operation. This is probably the most difficult group to deal with compared with those in whom an urgent operation is either clearly required, or clearly not required, and undoubtedly the one in which the majority of errors occur. Further urgent investigations are obviously important in this group and these are discussed in some detail elsewhere in this book. However, while these are taking place, a period of observation with regular review is essential. This period of observation has now become an integral part of the early management of patients with acute abdominal pain.

LEARNING OBJECTIVES

To know and understand:

- Basic anatomy of the abdominal wall and its weaknesses
- Causes of abdominal hernia
- Types of hernia and classifications
- Clinical history and examination findings in hernia
- Complications of abdominal hernia
- Non-surgical and surgical management of hernia – including mesh
- Complications of hernia surgery
- Other abdominal wall conditions

THE ABDOMINAL WALL

Basic anatomy and function related to pathology

The abdominal wall is a complex structure composed primarily of muscle, bone and fascia. Its major function is to protect the enclosed organs of the gastrointestinal and urogenital tracts but a secondary role is mobility, being able to flex, extend, rotate and vary its capacity. Flexibility requires elasticity and stretch which compromise abdominal wall strength.

The roof of the abdomen is formed by the diaphragm separating the thoracic cavity above with negative pressure from the abdomen below with positive pressure. Weakness of the diaphragm can lead to much of the bowel being drawn into the chest down this pressure gradient. The bony pelvis forms the floor of the cavity but a muscular central portion, the perineum, may also weaken and allow rectum, bladder and gynaecological organs to bulge downwards, a condition called prolapse.

The overall design of the abdominal muscles is best seen on a transverse computed tomography (CT) scan through the mid-abdomen. Posteriorly the muscles are strong, further supported by the vertebral column, ribs and pelvis. Two regions called the posterior triangles represent areas of weakness which can lead to rare lumbar hernias. Laterally there are three thin muscle layers whose fibres criss-cross for strength and flexibility. Surgeons can make use of these layers, by making releasing incisions, separating the layers and then sliding one layer on another to increase girth and allow closure of defects in the centre of the abdomen, e.g. the 'Ramirez slide' used in large incisional hernia repair (Figure 60.1).

Anteriorly the two powerful rectus abdominus muscles extend vertically from ribs to pelvis. Herniation through these strong muscles does not occur naturally but their central join, the linea alba, is an area of weakness resulting in epigastric and paraumbilical herniation. Divarification of the recti is the condition where the linea alba stretches laterally as the two rectus muscles

Figure 60.1 A cross section of the midabdomen showing the muscular layout.

separate. It occurs in the upper abdomen in middle-aged, overweight men (Figure 60.2) but also as a result of birth trauma in the female when it occurs below the umbilicus.

Abdominal pressure

The positive pressure within the abdomen is used by a surgeon when drains are placed to allow blood, pus, bile, bowel content and urine to flow outwards down the pressure gradient. However, this constant pressure from within can also lead to the condition of abdominal hernia where tissue, meant to be within the abdominal cavity, is forced outwards through defects in the muscular wall.

ABDOMINAL HERNIA

A hernia is the bulging of part of the contents of the abdominal cavity through a weakness in the abdominal wall.

Figure 60.2 Divarification.

Anatomical causes of abdominal wall herniation

Despite the complex design of the abdominal wall, the only natural weaknesses caused by inadequate muscular strength are the lumbar triangles and the posterior wall of the inguinal canal (Figure 60.3).

Many structures pass into and out of the abdominal cavity creating weakness which can lead to hernia formation. The most common example is the inguinal canal in the male along which the testis descends from abdomen to scrotum at the time of birth. The testicular artery, veins and vas pass through this canal (the round ligament in the female). The resultant weakness leads to an indirect or lateral-type inguinal hernia. In adult surgery, 80 per cent of all hernia repairs are for inguinal hernia. The evolutionary advantage of testicular descent must outweigh the disadvantage of a high risk of herniation. Other examples are: oesophagus → hiatus hernia, femoral vessels → femoral hernia, obturator nerve → obturator hernia, sciatic nerve → sciatic hernia.

An inguinal hernia (indirect) also occurs through the developmental failure of the processus vaginalis to close. As the testis descends, it pulls a tube of peritoneum along with it. This tube should naturally fibrose and become obliterated but often it fails to fibrose and allows a hernia to form. Recent studies have shown that calcitonin gene-related peptide and hepatocyte growth factor influence the closure of the processus raising the possibility of a hormonal cause of hernia development.

Figure 60.3 Posterior wall defect.

Failure of normal development may lead to weakness of the abdominal wall. Examples are diaphragmatic, umbilical and epigastric hernias. Muscles which should unite during development fail to form strong unions with hernia development at birth or in later life.

Herniation at the umbilicus has both components, i.e. weakness due to structures passing through the abdominal wall in fetal life and developmental failure of closure.

The risk of inguinal hernia is related to the anatomical shape of the pelvis and is higher in patients having a wider and shorter pelvis.

Weakness of abdominal muscles may be the result of sharp trauma. Most commonly, this results from abdominal surgery but also occurs after stabbing. A surgical scar, even with perfect wound healing, has only 70 per cent of the initial muscle strength. This loss of strength can result in herniation in at least 10 per cent of surgical incisions. Smaller laparoscopic port-site incisions have a hernia rate of 1 per cent. Increasing use of this surgical approach should lead to a fall in the incidence of incisional hernia.

Muscle damage by blunt trauma or tearing of the abdominal muscles requires exceptional force and is rare.

The sudden presence of a mass in the rectus muscle may be a rectus sheath haematoma, occasionally due to trauma but nowadays more often due to excessive anticoagulation therapy.

Primary muscle pathology and neurological conditions can lead to muscle weakness and occasionally present to the surgeon as a 'hernia' (Summary box 60.1).

Summary box 60.1

Causes of hernia

- Basic design weakness
- Weakness due to structures entering and leaving the abdomen
- Developmental failures
- Genetic weakness of collagen
- Sharp and blunt trauma
- Weakness due to ageing and pregnancy
- Primary neurological and muscle diseases
- ? Excessive intra-abdominal pressure

Pathophysiology of hernia formation

A normal abdominal wall has sufficient strength to resist high abdominal pressure and prevent herniation of content. Herniation has been attributed to high pressures from constipation, prostatic symptoms, excessive coughing in respiratory disease and obesity. However, it has been shown that hernia is no more common in Olympic weight lifters than the general population, suggesting that high pressure is not a major factor in causing a hernia. Many patients will first notice a hernia after excessive straining.

There is good evidence that hernia is a 'collagen disease' and due to an inherited imbalance in the types of collagen. This is supported by histological evidence and relationships between hernia and other diseases related to collagen, such as aortic aneurysm.

Hernia development is more common in pregnancy due to hormonally induced laxity of pelvic ligaments. It is also more common in the elderly due to degenerative weakness of muscles and fibrous tissue. A recent Swedish report has shown that inguinal hernia is less common in obese patients with hernia risk being negatively related to body mass index (BMI) contrary to widespread belief. Hernia is more common in smokers.

Common principles in abdominal hernia

An abdominal wall hernia has two essential components, a defect in the wall and content, that is tissue which has been forced outwards through the defect. The weakness may be entirely in muscle, such as an incisional hernia. It may also be in fascia, like an epigastric hernia through the linea alba. It may have a bony component, such as a femoral hernia. The weakness in the wall is usually the narrowest part of the hernia which expands into the subcutaneous fat outside of the muscle. The defect varies in size and may be very small or indeed very large. The nature of the defect is important to understanding the risk of hernia complications. A small defect with rigid walls traps the content and prevents it from freely moving in and out of the defect, increasing the risk of complications.

The content of the hernia may be tissue from the extraperitoneal space alone, such as fat within an epigastric hernia or urinary bladder in a direct inguinal hernia. However, if such a hernia enlarges then peritoneum may also be pulled into the hernia secondarily along with intraperitoneal structures such as bowel or omentum; a good example is a 'sliding type' of inguinal hernia.

More commonly, when peritoneum is lying immediately deep to the abdominal wall weakness, pressure forces the peritoneum through the defect and into the subcutaneous tissues. This 'sac' of peritoneum allows bowel and omentum to pass through the defect. In most cases, the intraperitoneal organs can move freely in and out of the hernia, a 'reducible' hernia, but if adhesions form or the defect is small, bowel can become trapped and unable to return to the main peritoneal cavity, an 'irreducible' hernia, with high risk of further complications. The narrowest part of the sac, at the abdominal wall defect, is called the 'neck of the sac'.

When tissue is trapped inside a hernia it is in a confined space. The narrow neck acts as a constriction ring impeding venous return and increasing pressure within the hernia. Resulting tension leads to pain and tenderness. If the hernia contains bowel then it may become 'obstructed', partially or totally. If the pressure rises sufficiently, arterial blood is not able to enter the hernia and the contents become ischaemic and may infarct. The hernia is then said to have 'strangulated'. The wall of the bowel perforates, releasing infected, toxic bowel content into the tissues and ultimately back into the peritoneal cavity. The risk of strangulation is highest in hernias which have a small neck of rigid tissue leading first to irreducibility and on to strangulation. The term 'incarcerated' is not clearly defined and used to imply a hernia which is irreducible and developing towards strangulation (Summary box 60.2).

In a special circumstance (Richter's hernia) only part of the bowel wall enters the hernia. It may be small and difficult or even impossible to detect clinically. Bowel obstruction may not be present but the bowel wall may still become necrotic and perforate with life-threatening consequences. Femoral hernia may present in this way often with diagnostic delay and high risk to the patient (Figure 60.4).

Summary box 60.2

Types of hernia by complexity

- Occult – not detectable clinically; may cause severe pain
- Reducible – a swelling which appears and disappears
- Irreducible – a swelling which cannot be replaced in the abdomen, high risk of complications
- Strangulated – painful swelling with vascular compromise, requires urgent surgery
- Infarcted – when contents of the hernia have become gangrenous, high mortality

An interstitial hernia occurs when the hernia extends between the layers of muscle and not directly through them. This is typical of a Spigelian hernia (see below under Spigelian hernia).

An internal hernia is a term used when adhesions form within the peritoneal cavity leading to abnormal pockets into which bowel can enter and become trapped. As there is no defect within the abdominal wall, the term 'hernia' is confusing.

Clinical history and diagnosis in hernia cases

Patients are usually aware of a lump on the abdominal wall under the skin. Self-diagnosis is common. The hernia is usually painless but patients may complain of an aching or heavy feeling. Sharp, intermittent pains suggest pinching of tissue. Severe pain should alert the surgeon to a high risk of strangulation. One should determine whether the hernia reduces spontaneously or needs to be helped. The patient should be asked about symptoms which might suggest bowel obstruction.

It is important to know if this is a primary hernia or whether it is a recurrence after previous surgery. Recurrent hernia is more difficult to treat and may require a different surgical approach.

General questions regarding the cardiac and respiratory systems are necessary to assess a patient's anaesthetic risk.

In a male with a groin hernia, history of prostatic symptoms indicates a high risk of postoperative urinary retention.

Intake of anticoagulants such as warfarin is important as this impacts on future surgery. Many hernia operations can be performed as a day case or single overnight stay, so that suitability for such treatment needs to be assessed, including home support, distance from the hospital, mobility levels, etc.

Examination for hernia

The patient should be examined lying down initially and then standing as this will usually increase hernia size. In some

Figure 60.4 Diagrammatic representation of gangrenous Richter's hernia from a case of strangulated femoral hernia.

cases no hernia will be apparent with the patient lying. The patient is asked to cough, when an occult hernia may appear. Divarification is best seen by asking a supine patient to simply lift his head off the pillow.

The overlying skin is usually of normal colour. If bruising is present this may suggest venous engorgement of the content. If there is overlying cellulitis then hernia content is strangulating and the case should be treated as an emergency.

In most cases a cough impulse is felt. Gentle pressure is applied to the lump and the patient is asked to cough. If an impulse is felt this is due to increased abdominal pressure being transmitted into the hernia. In cases where the neck is tight and the hernia irreducible there may be no cough impulse. This can lead to failure of diagnosis and is typical of femoral hernia where lack of an impulse leads the clinician to misdiagnose a lymph node. Cough impulse can also occur in a saphena varix (see Chapter 57) which may be referred to a surgeon as a suspected inguinal hernia. It is not unusual for a patient to describe an intermittent swelling but the surgeon finds nothing on examination. This is due to muscle tightening in an anxious patient (Summary boxes 60.3 and 60.4).

Summary box 60.3

Checks

- Reducibility
- Cough impulse
- Tenderness
- Overlying skin colour changes
- Multiple defects/contralateral side
- Signs of previous repair
- Scrotal content for groin hernia
- Associated pathology

Summary box 60.4

Examination

- A swelling with a cough impulse is not necessarily a hernia
- A swelling with no cough impulse may still be a hernia

If, on lying, the hernia does not reduce spontaneously, the surgeon asks the patient to attempt reduction as he may be well practised in this task while the surgeon might cause unnecessary discomfort. If neither the patient nor surgeon can reduce the hernia then treatment is more urgent. An irreducible hernia may influence the decision between open and laparoscopic surgery. With the hernia reduced, the surgeon assesses the size, rigidity and number of defects. Multiple defects may be present in incisional hernia.

Investigations for hernia

For most hernias, no specific investigation is required, the diagnosis being made on clinical examination. However, the patient may have symptoms suggesting a hernia but no hernia is found or have a swelling suggestive of hernia but with clinical uncertainty. It is important to be certain that any symptoms described are due to a hernia and not to coexisting pathology. There may

Figure 60.5 X-ray showing staples causing chronic pain after trans-abdominal preperitoneal repair.

also be a requirement for more detailed information than can be found by examination alone. Plain x-ray of the abdomen is of little value (Figure 60.5) although a hiatus hernia and diaphragmatic hernia may be seen on chest x-ray. Ultrasound scan may be helpful in cases of irreducible hernia, where the differential diagnosis includes a mass or fluid collection, or when the nature of the hernia content is in doubt. Ultrasound is very useful in the early postoperative period when a haematoma or seroma may develop and be difficult to distinguish from an early recurrence. Ultrasound is non-invasive and low cost but operator dependent.

Computed tomography scanning is helpful in complex incisional hernia, determining the number and size of muscle defects, identifying the content, giving some indication of presence of adhesions and excluding other intra-abdominal pathology such as ascites, occult malignancy, portal hypertension, etc.

Contrast barium radiology is occasionally useful in the absence of CT. Contrast may also be injected directly into the peritoneum, a herniogram, to identify an occult sac, especially in occult inguinal hernia. Magnetic resonance imaging (MRI) can help in the diagnosis of sportsman's groin where pain is the presenting feature and the surgeon needs to distinguish an occult hernia from an orthopaedic injury.

Laparoscopy itself may be used. In incisional hernia, initial laparoscopy may determine that a laparoscopic approach is feasible or not depending on the extent of adhesions. In inguinal hernia repair by the transabdominal route, initial laparoscopy can determine the presence of an occult contralateral hernia which has been described in up to 20 per cent of patients (Summary box 60.5).

Summary box 60.5

Investigations

- Plain x-ray – of little value
- Ultrasound scan – low cost, operator dependent
- CT scan – incisional hernia
- MRI scan – good in sportsman's groin with pain
- Contrast radiology – especially for inguinal hernia
- Laparoscopy – useful to identify occult contra lateral inguinal hernia

Management principles

An abdominal wall hernia does not necessarily require repair. A patient may request surgery for relief of symptoms of discomfort, cosmesis or to establish the diagnosis when in doubt. The surgeon should recommend repair when complications are likely, the most worrying being strangulation with bowel obstruction and bowel infarction. All cases of femoral hernia, with high risk of strangulation, should be repaired surgically. Any case of irreducible hernia, especially where there is pain and tenderness, should be offered repair unless coexisting medical factors place the patient at very high risk from surgery or anaesthesia. Increasing difficulty in reduction and increasing size are indications for surgery. Surgery should be offered to younger adult patients as symptoms and complications are likely over time (Summary box 60.6).

Summary box 60.6

Management

- Not all hernias require surgical repair
- Small hernias can be more dangerous than large
- Pain, tenderness and skin colour changes imply high risk of strangulation
- Femoral hernia should always be repaired

In reality, most patients with a hernia should be offered repair. In the elderly, if the hernia is asymptomatic, small in size, can be reduced easily and is not causing anxiety then observation alone should be sufficient. This policy, called 'watchful waiting' has been studied in asymptomatic inguinal hernia. One study reported such a policy to be safe but a second study was abandoned when a small number of patients developed strangulation. A truss can be used to control a hernia but few surgeons would recommend this approach. Small paraumbilical hernias are often seen. They cause few symptoms and usually contain fat or omentum with a very low risk of complications.

Large incisional hernias, particularly recurrent, present a major problem. Surgical repair is a complex procedure with significant risk of complications and later recurrence. When the neck is wide, the risk of strangulation is low. In the obese and elderly patient, these risks may outweigh the benefits of surgery and it is common for surgeons to adopt a conservative approach.

Any patient who presents with acute pain in a hernia, particularly if irreducible, should be offered surgery. Often, in a patient with an irreducible hernia, after admission to hospital and adequate analgesia, the hernia will reduce due to muscle relaxation. The likelihood of similar episodes is very high and surgery should be recommended at this admission or soon after.

Operative approaches to hernia

All surgical repairs follow the same basic principles:

- 1 reduction of the hernia content into the abdominal cavity with removal of any non-viable tissue and bowel repair if necessary;
- 2 excision and closure of a peritoneal sac if present or replacing it deep to the muscles;
- 3 reapproximation of the walls of the neck of the hernia if possible;
- 4 permanent reinforcement of the abdominal wall defect with sutures or mesh.

Reduction of hernia content is essential for a successful repair. It is rare that a surgeon fails to reduce the hernia but extensive dissection can lead to bowel injury sometimes requiring bowel resection with subsequent risks of infection and bowel anastomotic complications.

Excision and closure of the peritoneal sac is ideal but not essential. During laparoscopic repair of incisional hernia, surgeons will often leave the sac *in situ* after reducing hernia contents and simply fix a mesh over the neck to prevent recurrence. There is risk of fluid formation within the sac (seroma). This is a common complication in all forms of hernia repair. In lateral (indirect) inguinal hernia, most surgeons excise the peritoneal sac but some leading experts recommend that it be dissected from surrounding tissue and simply pushed back through the deep inguinal ring. In laparoscopic repair of inguinal hernias, surgeons simply pull the sac back into the abdominal cavity from within and do not excise it.

Closure of the abdominal wall defect is ideal but may not be possible when the defect is large or when tissues are rigid. Plastic surgical techniques have been developed to 'borrow' tissue from elsewhere in order to cover large muscle defects but usually at the cost of leaving a weak area elsewhere. Over the past 20 to 30 years, surgeons have realised that simple closure of a hernia defect by sutures alone leads to a high recurrence rate.

Additional reinforcement of the defect with a non-absorbable mesh is now widely practised in most hernia repairs and evidence has shown that recurrence rates have improved but recurrence still remains a problem. A recent large-scale study reported that mesh repair delays but does not prevent recurrence. With improved surgical techniques and new meshes it is hoped that recurrence after surgery will fall further. Mesh repair has become so important in hernia surgery that some understanding of mesh technology is essential for the modern surgeon.

Mesh in hernia repair

The term 'mesh' refers to prosthetic material, either a net or a flat sheet which is used to strengthen a hernia repair. Mesh can be used:

- to bridge a defect: the mesh is simply fixed over the defect as a tension-free patch;
- to plug a defect: a plug of mesh is pushed into the defect;
- to augment a repair: the defect is closed with sutures and the mesh added for reinforcement.

A well-placed mesh should have good overlap around all margins of the defect, at least 2 cm but up to 5 cm if possible. Suturing a mesh edge-to-edge into the defect (inlay), with no overlap, is not recommended. Mesh plug repairs have gained some popularity in small defects especially where overlap is hard to achieve. Plug operations are fast but plugs can form a dense 'meshoma' of plug and collagen. Other complications include migration, erosion into adjacent organs, fistula formation and chronic pain.

Mesh types

The wide array of meshes available can be classified as follows.

Gross structure

Net meshes are woven or knitted. Flat sheets are not porous but can be perforated with multiple holes. Net meshes allow fibrous tissue in growth between the strands and becoming

adherent and integrated into host tissues within a few months. Initial fixation of the mesh is by glue, sutures or staples which may be absorbable. In laparoscopic inguinal hernia, no fixation is required at all as friction is sufficient to hold the mesh. 'Sheet' meshes do not allow host tissue in-growth but become encapsulated by fibrous tissue. They always require strong, non-absorbable fixation to prevent mesh migration.

Synthetic mesh

The majority of meshes used today are synthetic polymers of polypropylene, polyester or polytetrafluoroethylene (PTFE) (Figure 60.6a,b). They are non-absorbable and provoke little tissue reaction. Polypropylene makes a strong monofilament mesh. It does not have any antibacterial properties but its hydrophobic nature and monofilament microstructure impede bacterial in-growth. Polyester is a braided filament mesh. This structure may allow infection to take hold, aided by its hydrophilic property. However this property also allows rapid vascular and cellular infiltration within the fibrils aiding host immune responses to infection and providing a stronger host–tissue interface. PTFE meshes are flat sheets and as a result do not allow any tissue in-growth. They are used as a non-adhesive barrier between tissue layers.

Weight and porosity

Synthetic meshes are very strong and early meshes were much stronger than a human abdominal wall so are considered as 'over-engineered'. All meshes provoke a fibrous reaction. More dense or heavyweight meshes provoke a greater reaction leading

to collagen contraction and stiffening. The term 'mesh shrinkage' is often used to describe a progressive decrease in size of a mesh over time. It is due to natural contraction of fibrous tissue embedded in the mesh, reducing the area of mesh itself. This can lead to tissue tension and pain, a common complication of mesh repair. It can also lead to hernia recurrence if the mesh no longer covers the defect. Meshes can shrink by up to 50 per cent and, in occasional cases, even more. Meshes with thinner strands and larger spaces between them, 'lightweight, large-pore meshes', are preferred as they have better tissue integration, less shrinkage, more flexibility and improved comfort.

The terms 'light, medium and heavy' are not precisely defined but meshes less than 40 g/m² are generally referred to as light and meshes more than 80 g/m² are heavy.

Biological mesh

There are 'biological meshes' which are sheets of sterilised, decellularised, non-immunogenic connective tissue. They derive from human or animal dermis, bovine pericardium or porcine intestinal submucosa. They provide a 'scaffold' to encourage neovascular in-growth and new collagen deposition. Host enzymes eventually break down the biological implant which is replaced and remodelled with 'normal' host fibrous tissue. The rates of enzymatic degradation and collagen deposition vary between products and also depend on the local environment of the mesh. In the presence of infection, some biological meshes rapidly break down and weaken before remodelling can occur. Others remain strong, their labyrinthine microstructure allowing vascular in-growth to aid infection resistance. The choice of biological mesh depends on the clinical situation for which it is to be used. They are expensive.

Absorbable meshes

There are also synthetic absorbable meshes, such as those made from polyglycolic acid fibre. They are used in temporary abdominal wall closure and to buttress sutured repairs. They have no current role in hernia repair as they absorb and induce minimal collagen deposition.

Tissue-separating meshes

Most meshes induce fibrosis and, if placed within the peritoneal cavity, promote unwanted adhesions. New meshes have been designed for intraperitoneal use. Most of these have very different surfaces, one being sticky and one being slippery. Good adherence and host–tissue in-growth is required on the parietal (muscle) side of the mesh but the opposite (bowel) side needs to prevent adhesions to bowel. Usually one side of the mesh is coated by material which prevents adhesions (Figure 60.7), such as polycellulose, collagen, PTFE, etc. A recent mesh made entirely of a sheet of condensed PTFE with multiple perforations can be used intraperitoneally as the peritoneum will grow in through its perforations while bowel will not adhere to its inside (Summary box 60.7).

Positioning the mesh

The strength of a mesh repair depends on host–tissue in-growth. Meshes should be placed on a firm, well-vascularised tissue bed with generous overlap of the defect. The mesh can be placed:

- just outside of the muscle in the subcutaneous space (onlay);
- within the defect (inlay) – only applies to mesh plugs in small defects;

Figure 60.6 (a) Polypropylene mesh in totally extraperitoneal (TEP) inguinal hernia repair and (b) polytetrafluoroethylene (PTFE) mesh in paraumbilical hernia repair.

Figure 60.7 Adhesions to mesh.

Summary box 60.7

Mesh characteristics

- Woven, knitted or sheet
- Synthetic or biological – mainly synthetic
- Light, medium or heavyweight – lightweight becoming more popular
- Large pore, small pore – large pore causes less fibrosis and pain
- Intraperitoneal use or not – non-adhesive mesh on one side
- Non-absorbable or absorbable – mainly non-absorbable

Figure 60.8 Diagrammatic representation of the various layers into which meshes are placed in ventral hernia repair.

- between fascial layers in the abdominal wall (intraparietal or sublay);
- immediately extraperitoneally, against muscle or fascia (also sublay);
- intraperitoneally.

At open surgery all of these planes are used but laparoscopic surgeons currently only use intraperitoneal or extraperitoneal planes (Figure 60.8).

Limitations to the use of mesh

The presence of infection limits the use of mesh, particularly heavyweight types. If a mesh becomes infected then it often needs to be removed. Some infected meshes can be salvaged using a combination of debridement of non-incorporated mesh, appropriate antibiotics and modern vacuum-assisted dressings.

Meshes are expensive, especially those for intraperitoneal use, but prices are falling and there are reports of low-cost solutions such as mosquito netting!

SPECIFIC HERNIA TYPES

Hernia sites are shown in Figure 60.9.

Inguinal hernia

The inguinal hernia, often referred to as a 'rupture' by patients, is the most common hernia in men and women but much more common in men. There are two basic types which are fundamentally different in anatomy, causation and complications. However, they are anatomically very close to one another, surgical repair techniques are very similar and ultimate reinforcement of the weakened anatomy is identical so they are often referred to together as inguinal hernia (Summary box 60.8).

Summary box 60.8

Inguinal hernia

- Types – lateral (oblique, indirect); medial (direct), sliding
- Origin – congenital or acquired
- Anatomy – inguinal canal
- Classification – latest European Hernia Society
- Diagnosis – usually clinical but radiological in special circumstances
- Surgery – open and laparoscopic

Figure 60.9 Diagram to show the sites of abdominal wall hernias, common in red and rare in black. Incisional and parastomal hernias can be found at various sites.

The congenital inguinal hernia is known as indirect, oblique or lateral while the acquired hernia is called direct or medial. There is a third 'sliding' hernia which is acquired but is lateral in position (see below).

Basic anatomy of the inguinal canal

As the testis descends from the abdominal cavity to the scrotum in the male it firsts passes through a defect called the deep inguinal ring in the transversalis fascia, just deep to the abdominal muscles. This ring lies midway between the anterior superior iliac spine and the pubic tubercle, approximately 2–3 cm above the femoral artery pulse in the groin. The inferior epigastric vessels lie just medial to the deep inguinal ring passing from the iliac vessels to the rectus abdominus muscle. Muscle fibres of the innermost two layers of the lateral abdominal wall, the transversus muscle and the internal oblique muscle, arch over the deep inguinal ring from lateral to medial before descending to become attached to the pubic tubercle. These two muscles fuse and become tendinous, hence this arch is referred to as the conjoint tendon. Below this arch there is no muscle but only transversalis fascia and external oblique aponeurosis resulting in weakness (Figure 60.10).

The testis proceeds medially and downwards along the inguinal canal. Anterior to the canal is the aponeurosis of the external oblique muscle whose fibres run downwards and medially. The testis finally emerges through a v-shaped defect in the aponeurosis, the superficial inguinal ring, and descends into the scrotum. The inguinal canal is roofed by the conjoint tendon, its posterior wall is transversalis fascia, an anterior wall is the external oblique aponeurosis and a floor which is also external oblique which rolls inwards at its lower margin and thickens to become the inguinal ligament (Poupart's). The inguinal canal in the male contains the testicular artery, veins, lymphatics and the vas deferens. In the female, the round ligament descends through the canal to end in the vulva. Three important nerves, the ilioinguinal, the iliohypogastric and the genital branch of the genitofemoral nerve also pass through the canal.

As the testis descends, a tube of peritoneum is pulled with the testis and wraps around it ultimately to form the tunica vaginalis. This peritoneal tube should obliterate, possibly under hormonal control, but it commonly fails to fuse either in part or totally. As a result, bowel within the peritoneal cavity is able to pass inside the tube down towards the scrotum. Inguinal hernia in neonates

Figure 60.10 The close relationships of direct inguinal, indirect inguinal and femoral hernias.

and young children is always of this congenital type. However, in other patients, the muscles around the deep inguinal ring are able to prevent a hernia from developing until later in life, when under the constant positive abdominal pressure, the deep inguinal ring and muscles are stretched and a hernia becomes apparent. As the hernia increases in size, the contents are directed down into the scrotum. These hernias can become massive and may be referred to as a scrotal hernia (Figure 60.11).

An indirect hernia is lateral as its origin is lateral to the inferior epigastric vessels. It is also oblique as the hernia passes obliquely from lateral to medial through the abdominal muscle layers.

The second type of inguinal hernia, referred to as direct or medial, is acquired. It is a result of stretching and weakening of the abdominal wall just medial to the inferior epigastric (IE) vessels. Looked at from within the abdominal cavity, there is a triangle referred to as Hasselbach's triangle, whose three sides are the IE vessels laterally, the lateral edge of the rectus abdominus muscle medially and the pubic bone below (the iliopubic tract) (Figure 60.12). This area is weak as the abdominal wall here only consists of transversalis fascia covered by the external oblique aponeurosis. A direct, medial hernia is more likely in elderly

Figure 60.11 A huge scrotal hernia that has descended into the scrotum. The overlying skin has become gangrenous and sloughed away (courtesy of Dr Anupam Rai, Jabalpur, India).

Figure 60.12 Laparoscopic view of posterior inguinal region with hernia defects highlighted: yellow – medial inguinal; blue – lateral inguinal; green – femoral.

patients. It is broadly based and therefore unlikely to strangulate. The medially placed bladder can be pulled into a direct hernia (Figure 60.13).

The third type of inguinal hernia is referred to as a sliding hernia. This is also an acquired hernia due to weakening of the abdominal wall but this occurs at the deep inguinal ring lateral to the IE vessels. Retroperitoneal fatty tissue is pushed downwards along the inguinal canal. As more tissue enters the hernia, peritoneum is pulled with it, thus creating a sac. However the sac has formed secondarily, distinguishing it from a classic indirect hernia. On the left side, sigmoid colon may be pulled into a sliding hernia and on the right side the caecum. Surgeons need extra caution during repair as the wall of the large bowel may not be covered by peritoneum and can be damaged.

Occasionally, both lateral and medial hernias are present in the same patient (pantaloon hernia).

Figure 60.13 This cystogram shows the urinary bladder, part of which has descended into a left direct inguinal hernia.

Classification

Many surgeons over the past hundred years have attempted to classify inguinal (and femoral) hernias, including Casten, Halverson and McVay, Zollinger, Ponka, Gilbert and Nyhus. The European Hernia Society has recently suggested a simplified system of:

- primary or recurrent (P or R);
- lateral, medial or femoral (L, M or F);
- defect size in finger breadths assumed to be 1.5 cm.

A primary, indirect, inguinal hernia with a 3-cm defect size would be PL2.

Diagnosis of an inguinal hernia

In most cases, the diagnosis of an inguinal hernia is simple and patients often know their diagnosis as they are so common. Usually these hernias are reducible presenting as intermittent swellings, lying above and lateral to the pubic tubercle with an associated cough impulse. Often the hernia will reduce on lying and reappear on standing. With the patient lying down, the patient is asked to reduce the hernia if it has not spontaneously reduced. If the patient cannot then the surgeon gently attempts to reduce the hernia. Once reduced, the surgeon identifies the bony landmarks of the anterior superior iliac spine and pubic tubercle to landmark the deep inguinal ring at the mid-inguinal point. Gentle pressure is applied at this point and the patient asked to cough. If the hernia is controlled with pressure on the

deep inguinal ring then it is likely to be indirect/lateral and if the hernia appears medial to this point then it is direct/medial. Other examination techniques have been suggested but even experienced surgeons find it difficult to distinguish lateral and medial hernias with certainty (Figure 60.14).

Diagnostic difficulties

Confirmation of the diagnosis may not be possible when the patient describes an intermittent swelling but nothing is found on examination. Surgeons will often accept the diagnosis on history alone but re-examination at a later date or investigation by ultrasound scan may be requested.

If an inguinal hernia becomes irreducible and tense there may be no cough impulse. Differential diagnosis would include a lymph node groin mass or an abdominal mass. Such cases require urgent investigation by either ultrasound or CT scan (Figure 60.15).

Large scrotal hernias may be misdiagnosed as a hydrocoele or other testicular swelling. The surgeon should be able to identify the upper limit of a scrotal swelling but a large scrotal hernia has no upper limit as it extends back along the inguinal canal to the

Figure 60.14 Oblique left inguinal hernia that became apparent when the patient coughed and persisted until it was reduced when he lay down.

Figure 60.15 Malignant mass of nodes.

peritoneal cavity. In cases of doubt, ultrasound scanning should establish the diagnosis.

As inguinal hernia is so common, less-experienced clinicians might suggest this diagnosis when referring cases of femoral hernia or spigelian hernia. Also patients with a saphena varix may present with a swelling which increases in size on standing and with a definite cough impulse and be misdiagnosed as a hernia. The same can be true for a varicocoele.

It is essential to examine the scrotal contents to exclude other pathologies and to check that the patient has two testes. It is important to examine the opposite side as contralateral hernia is common. Even if the contralateral side is weak, then bilateral repair should be recommended as the risk of contralateral recurrence is high. Ten per cent of all patients will present with bilateral inguinal hernias and up to 20 per cent more will have an occult contralateral hernia on laparoscopic evaluation. A patient with a single hernia has a lifetime 33 per cent risk of developing a hernia on the other side. Some surgeons have suggested that all patients should be offered bilateral repair especially if laparoscopic surgery is planned, but this is not widespread practice at present.

Investigations for inguinal hernia

Most cases require no diagnostic tests but ultrasound scanning, CT scan and MRI scan are occasionally used. A herniogram involves the injection of contrast into the peritoneal cavity followed by screening which shows the presence of a sac or asymmetric bulging of the inguinal anatomy.

Management of inguinal hernia

It is safe to recommend no active treatment in cases of early, asymptomatic, direct hernia, particularly in elderly patients who do not wish surgical intervention. These patients should be warned to seek early advice if the hernia increases in size or becomes symptomatic. Surgical trusses are not recommended but may be required for occasional patients who refuse any form of surgical intervention.

Elective surgery for inguinal hernia is a common and simple operation. It can be undertaken under local, regional or general anaesthesia with minimal risk even in high-risk patients.

Herniotomy

In children who have lateral hernias with a persistent processus, it is sufficient only to remove and close the sac. This is called a herniotomy. In adult surgery, herniotomy alone has a high recurrence rate and some form of muscle strengthening is added (herniorrhaphy).

Open suture repair

In 1890, Eduardo Bassini described suture repair for inguinal hernia (Figure 60.16). This was a massive leap forward and has been the basis of open repair for over 100 years. The surgeon enters the inguinal canal by opening its anterior wall, the external oblique aponeurosis. The spermatic cord is dissected free and the presence of a lateral or a medial hernia is confirmed. The sac of a lateral hernia is separated from the cord, opened and any contents reduced. The sac is then sutured closed at its neck and excess sac removed. If there is a medial hernia then it is inverted and the transversalis fascia is suture plicated. Sutures are now placed between the conjoint tendon above and the inguinal ligament below, extending from the pubic tubercle to the deep

Figure 60.16 Bassini's original diagram. A, subcutaneous fat; B, external oblique; C, iliac vein; E, spermatic cord; F, nerves in inguinal canal; G, transversalis fascia.

inguinal ring. The posterior wall of the inguinal canal is thus strengthened.

Over 150 modifications to the Bassini operation have been described with little or no benefit except for the Shouldice modification. In this operation, the transversalis fascia is opened by a central incision from the deep inguinal ring to the pubic tubercle and then closed to create a double-thick, two-layered posterior wall (double breasting). The external oblique is closed in similar fashion. Expert centres have reported lifetime failure rates of less than 2 per cent after Shouldice repair but it is a technically demanding operation which, in general hands, gives results identical to the Bassini repair.

Today, when a Bassini-type operation is done, most surgeons use a continuous, non-absorbable nylon or polypropylene suture which is darned between the conjoint tendon and inguinal ligament. This operation was described by Maloney, and recently published large randomised trials have reported excellent results when compared to mesh techniques. It is the most common operation performed in countries where mesh is too expensive.

Suture repair is still under development, and recently, Desarda has described an operation where a 1–2-cm strip of external oblique aponeurosis lying over the inguinal canal is isolated from the main muscle but left attached both medially and laterally. It is then sutured to the conjoint tendon and inguinal ligament, reinforcing the posterior wall of the inguinal canal. As the abdominal muscles contract, this strip of aponeurosis tightens to add further physiological support to the posterior wall. This operation is currently being evaluated.

Open flat mesh repair

Synthetic mesh has been used since the 1950s to reinforce hernia repair, and in the 1980s Lichtenstein described a tension-free, simple, flat, polypropylene mesh repair for inguinal hernia (Figure 60.17). The initial part of the operation is identical to Bassini. Once the hernia sac has been removed and any medial defect closed, a piece of mesh, measuring 8 × 15 cm, is placed over the posterior wall, behind the spermatic cord, and is split to wrap around the spermatic cord at the deep inguinal ring. Loose sutures hold the mesh to the inguinal ligament and conjoint tendon. Two major advantages are claimed: lowered

Figure 60.17 Lichtenstein repair.

hernia recurrence rates and accelerated postoperative recovery. Randomised trials show that hernia recurrence within the first two years is lowered but acute pain scores are similar. Recent research comparing the Lichtenstein repair with laparoscopic surgery has identified chronic pain as the most common complication of open flat mesh repair with rates reported as high as 20 per cent. Nonetheless, today, the Lichtenstein repair is the most common operation for inguinal hernia in the developed world.

Open plug/device/complex mesh repair

Surgeons and industry have been highly creative, attempting to improve on simple flat mesh repair. A surgeon in Europe has over 200 different products and techniques from which to choose. Shaped mesh plugs have gained much attention being simple to insert into the defect and requiring little if any fixation. However, they can become solid (meshoma) and also migrate. Meshes have been designed to be placed beneath the transversalis fascia. The surgeon introduces a finger through the deep inguinal ring and bluntly (and blindly) opens the preperitoneal space deep to the inguinal canal into which a mesh is inserted. A two-layered mesh ('hernia system'), in which the inner layer is placed deep to transversalis fascia and the outer layer superficial to it, is also gaining popularity. To date, there is little evidence to show any of these techniques is superior to the Lichtenstein operation.

Open preperitoneal repair

This approach was first described by Annandale in 1880, but was largely discarded until the 1950s when Stoppa, a French surgeon, described it with mesh reconstruction. It is useful when multiple attempts at open standard surgery have failed and the hernia(s) keeps recurring. It may now be superseded by the totally extraperitoneal laparoscopic approach which is modelled on the Stoppa operation and first described by Ger, also French.

Laparoscopic inguinal hernia repair

Two techniques are described and have been extensively studied in randomised trials. The totally extraperitoneal (TEP) approach is more widely used than the transabdominal preperitoneal (TAPP) approach. In both, the aim of surgery is to reduce the hernia and hernia sac within the abdomen and then place a 10 × 15 cm mesh just deep to the abdominal wall, extending across the midline into the retropubic space and 5 cm lateral to the deep inguinal ring. The mesh covers Hasselbach's triangle,

the deep inguinal ring and the femoral canal. In TEP, the surgeon is able to create a space just deep to the abdominal muscles without entering the peritoneal cavity whereas, in TAPP, the surgeon enters the peritoneal cavity then incises the peritoneum above the hernia defects and reflects it away from the muscles, essentially entering the same space as in TEP. Once the hernia is reduced, an identical mesh is inserted and the peritoneum closed over the mesh (Figures 60.18 and 60.19).

Over 60 randomised trials have compared laparoscopic surgery with the Lichtenstein repair. They show that, although the laparoscopic operation takes longer to perform, proven advantages are reduced pain both following surgery and up to five years later, more rapid return to full activity and reduced incidence of the wound complications of infection, bleeding and seroma. Laparoscopic surgery is of particular benefit in bilateral cases and in patients with hernia recurrence after open surgery. National statistics show that the proportion of cases performed laparoscopically is slowly rising but all agree that there is a slow learning curve associated with these technically demanding operations (Summary box 60.9).

Emergency inguinal hernia surgery

Ninety-five per cent of inguinal hernia patients present at clinics and only 5 per cent present as an emergency with a painful irreducible hernia which may progress to strangulation and possible bowel infarction. The morbidity and mortality of emergency inguinal hernia surgery is high and surgery needs to be performed rapidly in a well-resuscitated patient with adequate postoperative high dependency or intensive care if necessary. The principles of surgery are the same as in an elective setting. Open surgery is preferred when a hernia is irreducible or if there is any risk of bowel resection. Infection may complicate these cases but most surgeons would still use a lightweight, synthetic mesh repair covered by appropriate antibiotics.

Complications of inguinal hernia surgery

Despite this being a common procedure and technically straightforward, postoperative complications are common. Immediate complications include bleeding (which may be due to accidental damage to the inferior epigastric or iliac vessels) and urinary retention which may require catheterisation. Occasional over-enthusiastic infusion of local anaesthetic may lead to femoral nerve blockade, the patient being unable to move a leg. This usually resolves over 12 hours but is alarming.

Over the next week, seroma formation and wound infection may occur. Seroma is due to an excessive inflammatory response to sutures or mesh and cannot be prevented. In most cases the fluid resolves spontaneously but may require aspiration. After laparoscopic surgery, a seroma may be misdiagnosed as an early recurrence. Wound infection is not uncommon. Many surgeons use routine prophylactic antibiotics but recent studies suggest little benefit even when mesh is used.

In the longer term, hernia recurrence and chronic pain are the main concerns. No operation can guarantee to be recurrence free. Evidence shows that mesh repairs have lower recurrence rates than suture repairs but there is no difference between the various mesh repairs and no difference between open and laparoscopic surgery. There is very strong evidence that specialist hernia surgeons will have lower recurrence rates whatever technique they use.

Chronic pain, defined as pain present three months after surgery, is common after all forms of surgery. It is less common and less severe after laparoscopic surgery. Different types of pain have been described but the most severe is neuralgic pain due to nerve irritation. This may be the result of nerve injury at the

time of operation or chronic irritation of nerves by suture material or mesh. Careful identification and protection of all three nerves passing along the inguinal canal reduces the incidence of neuralgic pain. This type of pain is also very uncommon after laparoscopic surgery which is performed at a deeper level away from the nerves. Some contribution to chronic pain may be due to the mesh which can become embedded in a dense collagenous reaction with shrinkage. This causes tissue tension and rigidity.

Rarely, damage to the testicular artery can lead to testicular infarction, perhaps the most serious complication of inguinal hernia surgery. There is no good evidence that hernia surgery has an effect on male fertility despite extensive study in this area (Summary box 60.10).

Summary box 60.10

Complications

- Early – pain, bleeding, urinary retention, anaesthetic related
- Medium – seroma, wound infection
- Late – chronic pain, testicular atrophy

Sportsman's hernia

This specific entity is well described and presents as severe pain in the groin area, extending into the scrotum and upper thigh. It is almost entirely restricted to young men who play contact sports such as football and rugby. The pain can be debilitating and prevent the patient from exercising. On examination there may be some tenderness in the region of the inguinal canal, over the pubic tubercle and over the insertion of the thigh adductor muscles. Usually no hernia can be felt and only occasionally can a true inguinal hernia be found.

In most cases, the pain is due to an orthopaedic injury, such as adductor strain or pubic symphysis diastasis. However, some believe that it can be due to muscle tearing (Gilmore's groin) or stretching of the posterior wall of the inguinal canal. Other causes of pain should be excluded, such as hip, pelvic or lumbar spinal disease and bladder/prostate problems. MRI scanning is most likely to detect an orthopaedic problem but ultrasound, hysterniography or even laparoscopy may be used.

There are many anecdotal reports of successful treatment using all types of inguinal hernia surgery, suture and mesh, open and laparoscopic, but no randomised trials. Hernia surgery should be a last resort and the patient warned of a significant risk of failure to cure the pain.

Femoral hernia

Basic anatomy

The iliac artery and vein pass below the inguinal ligament to become the femoral vessels in the leg. The vein lies medially and the artery just lateral to the artery with the femoral nerve lateral to the artery. They are enclosed in a fibrous sheath. Just medial to the vein is a small space containing fat and some lymphatic tissue (node of Cloquet). It is this space which is exploited by a femoral hernia. The walls of a femoral hernia are the femoral vein laterally, the inguinal ligament anteriorly, the pelvic bone covered by the

Sir Astley Paston Cooper, 1768–1841, surgeon, Guy's Hospital, London, UK. He received a baronetcy and one thousand guineas for successfully removing an infected wen from the head of King George IV at Brighton in 1821.

Figure 60.20 Left femoral hernia – laparoscopic view. Note the iliac vein left and lateral to the femoral hernia defect.

ileopectineal ligament (Astley Cooper's) posteriorly and the lacunar ligament (Gimbernat's) medially. This is a strong curved ligament with a sharp unyielding edge which impedes reduction of a femoral hernia (Figure 60.20).

The female pelvis has a different shape to the male, increasing the size of the femoral canal and the risk of hernia. In old age, the femoral defect increases and femoral hernia is commonly seen in low-weight, elderly females. There is a substantial risk of developing a femoral hernia after a sutured inguinal hernia repair (Denmark Hernia Registry) (Summary box 60.11).

Summary box 60.11

Femoral hernia

- Less common than inguinal hernia
- It is more common in females than in males
- Easily missed on examination
- Fifty per cent of cases present as an emergency with very high risk of strangulation

Diagnosis of femoral hernia

Diagnostic error is common and often leads to delay in diagnosis and treatment. The hernia appears below and lateral to the pubic tubercle and lies in the upper leg rather than in the lower abdomen. Inadequate exposure of this area during routine examination leads to failure to detect the hernia. The hernia often rapidly becomes irreducible and loses any cough impulse due to the tightness of the neck. It may only be 1–2 cm in size and can easily be mistaken for a lymph node. As it increases in size, it is reflected superiorly and becomes difficult to distinguish from a medial direct hernia which arises only a few centimetres above the femoral canal. A direct inguinal hernia leaves the

Figure 60.21 The patient has a left femoral and a right inguinal hernia.

abdominal cavity just above the inguinal ligament and a femoral hernia just below (Figure 60.21) (Summary box 60.12).

Investigations

In routine cases, no specific investigations are required. However, if there is uncertainty then ultrasound or CT should be requested. In the emergency patient, bowel obstruction usually occurs and a plain x-ray is likely to show small bowel obstruction. All patients with unexplained small bowel obstruction should undergo careful examination for a femoral hernia. It is now common to perform CT scanning in cases of bowel obstruction primarily to exclude malignancy, but it can identify an obstructing femoral hernia missed by clinicians.

Surgery for femoral hernia

There is no alternative to surgery for femoral hernia and it is wise to treat such cases with some urgency. There are three open approaches and appropriate cases can be managed laparoscopically.

Low approach (Lockwood)

This is the simplest operation for femoral hernia but only suitable when there is no risk of bowel resection. It can easily be performed under local anaesthesia. A transverse incision is made over the hernia. The sac of the hernia is opened and its contents reduced. The sac is also reduced and non-absorbable sutures placed between the inguinal ligament above and the fascia overlying the bone below. A small incision can be made in the medial lacunar ligament to aid reduction but there may be an abnormal branch of the obturator artery just deep to it which can bleed. The femoral vein, lateral to the hernia, needs to be protected. Some surgeons place a mesh plug into the hernia defect for further re-enforcement.

The inguinal approach (Lotheissen)

The initial incision is identical to that of a Bassini or Lichtenstein operation into the inguinal canal. The spermatic cord (or round ligament) is mobilised and the transversalis fascia opened from deep inguinal ring to pubic tubercle. A femoral hernia lies immediately below this incision and can be reduced by a combination of pulling from above and pushing from

below. If necessary, the peritoneum can be opened to help with reduction. Once reduced, the neck of the hernia is closed with sutures or a mesh plug, protecting the iliac vein throughout. The layers are closed as for inguinal hernia and the surgeon may place a mesh into the inguinal canal to protect against development of an inguinal hernia.

Some surgeons believe that exploration of the femoral canal to exclude a hernia should be a routine part of inguinal hernia surgery but most surgeons do not do this.

High approach (McEvedy)

This more complex operation is ideal in the emergency situation where the risk of bowel strangulation is high. It requires regional or general anaesthesia. A horizontal incision (classically vertical) is made in the lower abdomen centred at the lateral edge of the rectus muscle. The anterior rectus sheath is incised and the rectus muscle displaced medially. The surgeon proceeds deep to the muscle in the preperitoneal space. The femoral hernia is reduced and the sac opened to allow careful inspection of the bowel, and a decision made regarding the need for bowel resection. This is performed if necessary. In dubious cases, the bowel is replaced into the peritoneal cavity for 5 minutes and then re-examined. The femoral defect is then closed with sutures, mesh or plug. This approach allows a generous incision to be made in the peritoneum which aids inspection of the bowel and facilitates bowel resection.

Laparoscopic approach

Both the TEP and TAPP approaches can be used for femoral hernia and a standard mesh inserted. This is ideal for reducible femoral hernias presenting electively but not in emergency cases nor for irreducible hernia.

VENTRAL HERNIA

This term refers to hernias of the anterior abdominal wall. Inguinal and femoral hernias are not included even though they are ventral. Lumbar hernia is included despite being dorsolateral. The European Hernia Society classification (2009) distinguished primary ventral from incisional hernia but did not include parastomal hernia. We have included parastomal hernia and traumatic hernia (Summary box 60.13).

Summary box 60.13

Ventral hernias

- Umbilical – paraumbilical
- Epigastric
- Incisional
- Parastomal
- Spigelian
- Lumbar
- Traumatic

Umbilical hernia

The umbilical defect is present at birth but closes as the stump of the umbilical cord heals, usually within a week of birth. This process may be delayed, leading to the development of herniation in the neonatal period. The umbilical ring may also stretch and reopen in adult life.

Umbilical hernia in children

This common condition occurs in up to 10 per cent of infants, with a higher incidence in premature babies. The hernia appears within a few weeks of birth and is often symptomless but increases in size on crying and assumes a classical conical shape. Sexes are equally affected but the incidence in black infants is up to eight times higher than in white. Obstruction and/or strangulation are extremely uncommon below the age of three years.

Treatment

Conservative treatment is indicated under the age of two years when the hernia is symptomless. Parental reassurance is all that is necessary. Ninety-five per cent of hernias will resolve spontaneously. If the hernia persists beyond the age of two years it is unlikely to resolve and surgical repair is indicated.

Operation

A small curved incision is made immediately below the umbilicus. The neck of the sac is defined, opened and any contents are returned to the peritoneal cavity. The sac is closed and redundant sac is excised. The defect in the linea alba is closed with interrupted sutures (Summary box 60.14).

Summary box 60.14

Umbilical hernia in children

- Common in infants and most resolve spontaneously
- Rarely strangulate

Umbilical hernia in adults

Conditions which cause stretching and thinning of the mid-line raphe (linea alba), such as pregnancy, obesity and liver disease with cirrhosis, predispose to reopening of the umbilical defect. In adults, the defect in the median raphe is immediately adjacent to (most often above) the true umbilicus, although at operation this is indistinguishable. The term paraumbilical hernia is commonly used (Figure 60.22). The defect is rounded with a well-defined fibrous margin. Small umbilical hernias often contain extraperitoneal fat or omentum. Larger hernias can contain small or large bowel but, even when very large, the neck of the sac is narrow compared with the volume of its contents. As a result, in adults, umbilical hernias which include

Figure 60.22 A small paraumbilical hernia.

bowel are prone to become irreducible, obstructed and strangulated.

Clinical features

Patients are commonly overweight with a thinned and attenuated midline raphe. The bulge is typically slightly to one side of the umbilical depression, creating a crescent-shaped appearance to the umbilicus (Figure 60.23). Women are affected more than men. Most patients complain of pain due to tissue tension or symptoms of intermittent bowel obstruction. In large hernias, the overlying skin may become thinned, stretched and develop dermatitis.

Treatment

Because of the high risk of strangulation, operation should be advised in cases where the hernia contains bowel. Small hernias may be left alone if they are asymptomatic, but they may enlarge and require surgery at a later date. Surgery may be performed open or laparoscopically.

Open umbilical hernia repair

Very small defects less than 1 cm in size may be closed with a simple figure-of-eight suture, or repaired by a darn technique where a non-absorbable, monofilament suture is criss-crossed across the defect and anchored firmly to the fascia all around.

Defects up to 2 cm in diameter may be sutured primarily with minimal tension, although the larger the defect, the more tension and the more likely it is that mesh reinforcement will be beneficial. The classical repair was described by Mayo. A transverse incision is made and the hernia sac dissected, opened and its content reduced. Any non-viable tissue is removed, sometimes involving bowel resection. The peritoneum is closed. The defect in the anterior rectus sheath is extended laterally on both sides and elevated to create an upper and lower flap. The lower flap is then inserted beneath the upper flap and sutured to it, with the upper flap being brought downwards over it so that the

Figure 60.23 A large paraumbilical hernia.

William James Mayo, 1861–1939, surgeon, the Mayo Clinic, Rochester, MN, USA, described this operation in 1901. He and his brother Charles Horace Mayo (1865–1939) joined their father's private practice in Rochester. This practice became the Mayo Clinic. Their father William Worrall Mayo was born in Manchester, UK in 1919.

tissue is two-layered (double breasted). Non-absorbable sutures are used. There is often a large subcutaneous space. A suction drain is placed to reduce the risk of seroma and haematoma. The skin is closed but stretched or redundant skin may need to be excised (apronectomy) to achieve a better cosmetic result. Today, with modern suture materials, surgeons simply close the anterior sheath in a single layer.

For defects larger than 2 cm in diameter, mesh repair is recommended (Figure 60.24). The mesh may be placed in one of several anatomical planes:

- Within the peritoneal cavity – a tissue separating mesh is placed through the defect and spread out on the underside of the abdominal wall and fixed to it, ideally, with an overlap of 5 cm in each direction. This is a quick repair but requires the use of expensive mesh.
- In the retromuscular space – the linea alba is opened both vertically and both left and right posterior rectus sheaths are incised 1 cm to the side of the midline exposing the rectus muscle. The posterior sheaths are sutured together and the muscles elevated away from the sheath to develop the retromuscular space into which a sheet of mesh is placed and fixed by sutures. The mesh should overlap the midline by 5 cm laterally and the umbilicus vertically. It should therefore be a minimum diameter of 10 cm. A drain may be placed deep to the linea alba. This is a very secure repair but requires extensive dissection.
- In the extraperitoneal space – it is difficult, but possible, to develop the plane below the posterior rectus sheath, just outside the peritoneum. Care must be taken to avoid 'button-holing' the peritoneum as it is thin and fragile. Mesh can then be tucked into in this space, ensuring a good overlap as before. Ideally, the linea alba is closed over the mesh but if this is not possible, a flap of peritoneal sac can be used to cover the mesh. This is a good repair, but if the peritoneum is extensively damaged during the dissection, it will have to be abandoned in favour of an alternative technique.
- In the subcutaneous plane – this is the simplest technique, called an onlay mesh. The peritoneal sac and contents are dealt with as above. An attempt is made to close linea alba vertically with sutures and a disc of mesh is placed on the anterior rectus sheath and sutured to it. The mesh is lying in the subcutaneous space and is prone to infection.

Figure 60.24 A massive paraumbilical hernia – operative view.

Laparoscopic umbilical hernia repair

Three ports are placed laterally on the abdominal wall, usually on the left side unless adhesions from previous surgery are likely. The contents of the hernia are reduced by traction and external pressure. The falciform ligament above and the median umbilical fold below may need to be taken down if they interfere with mesh placement. A disc of non-adherent mesh, designed for intraperitoneal use, is introduced and positioned on the under surface of the abdominal wall, centred on the defect. It is then fixed to the peritoneum and posterior rectus sheaths using staples, tacks or sutures. This is a simple and secure repair which achieves generous overlap without surgical damage to umbilicus and surrounding fascia (Figure 60.25). However, it requires specialised equipment and expensive tissue-separating mesh. Intraperitoneal meshes can cause severe pain lasting for 24–48 hours after surgery which can mimic peritonitis.

Figure 60.25 Paraumbilical defect – laparoscopic view.

Emergency repair of umbilical hernia

Incarceration, bowel obstruction and strangulation are frequent because of the narrow neck and the fibrous edge of the defect in the midline raphe. Delay to surgery can lead to gangrene of omentum or bowel. Large hernias are often multiloculated and there may be strangulated bowel in one component when other areas are clinically soft and non-tender hernia.

Operation

In cases of simple incarceration without clinical evidence of strangulation, repair may be attempted laparoscopically but reduction of the contents can be very difficult if the hernia contains bowel. The majority of emergency repairs are performed by open surgery. In the presence of established strangulation it is unwise to place mesh at all because of the risk of infection, so an open sutured repair should be performed, accepting a high risk of later recurrence. Alternatively, a two-stage repair could be planned: the hernia contents being dealt with initially with little attempt made to close the defect and then subsequent definitive mesh repair once sepsis has been controlled (Summary box 60.15).

Summary box 60.15

Umbilical hernia in adults

- Common in overweight men or multiparous women
- Progressively increase in size and may get very large indeed
- Round defect with rigid fibrous margins
- Surgery advised because of risk of obstruction and strangulation

Epigastric hernia

These arise through the midline raphe (linea alba) anywhere between the xiphoid process and the umbilicus, usually midway. When close to the umbilicus they are called supraumbilical hernias. Epigastric hernias begin with a transverse split in the midline raphe so, in contrast to umbilical hernias, the defect is elliptical. It has been hypothesised that the defect occurs at the site where small blood vessels pierce the linea alba or, more likely, that it arises at weaknesses due to abnormal decussation of aponeurotic fibres related to heavy physical activity (Figure 60.26).

Epigastric hernia defects are usually less than 1 cm in maximum diameter and commonly contain only extraperitoneal fat which gradually enlarges, spreading in the subcutaneous plane to resemble the shape of a mushroom. When very large they may contain a peritoneal sac but rarely any bowel. More than one hernia may be present. The most common cause of 'recurrence' is failure to identify a second defect at the time of original repair.

Clinical features

The patients are often fit, healthy males between 25 and 40 years of age. These hernias can be very painful even when the swelling is the size of a pea due to the fatty contents becoming nipped sufficiently to produce partial strangulation. The pain may mimic that of a peptic ulcer but symptoms should not be ascribed to the hernia until gastrointestinal pathology has been excluded. A soft midline swelling can often be felt more easily than it can be seen. It may be locally tender. It is unlikely to be reducible because of the narrow neck. It may resemble a lipoma. A cough impulse may or may not be felt.

Figure 60.26 Epigastric hernia – external view.

Treatment

Very small epigastric hernias have been known to disappear spontaneously, probably due to infarction of the fat. Small to moderate-sized hernias without a peritoneal sac are not inherently dangerous and surgery should only be offered if the hernia is sufficiently symptomatic.

Operation

This may be done by open or laparoscopic surgery. At open surgery, a vertical or transverse incision is made over the swelling and down to the linea alba. Protruding extraperitoneal fat can simply be pushed back through the defect or excised. Often a small vessel is present in the hernia content which can cause troublesome bleeding. The defect in the linea alba is closed with non-absorbable sutures in adults and absorbable sutures in children. In larger hernias and when a peritoneal sac is present, the surgical approach is similar to an umbilical mesh repair.

Laparoscopic repair is very similar to that for umbilical hernia except that the defect is hidden behind the falciform ligament which must be taken down from the undersurface of the abdominal wall. The margins of the defect must be clearly exposed and the fatty contents reduced before the mesh is placed. Simply placing a mesh under the linea midline may not in fact remove the hernia when its contents are extraperitoneal fat.

Incisional hernia

These arise through a defect in the musculofascial layers of the abdominal wall in the region of a postoperative scar. Thus they may appear anywhere on the abdominal surface.

Incidence and aetiology

Incisional hernias have been reported in 10–50 per cent of laparotomy incisions and 1–5 per cent of laparoscopic port-site incisions. Factors predisposing to their development are patient factors (obesity, general poor healing due to malnutrition, immunosuppression or steroid therapy, chronic cough, cancer), wound factors (poor quality tissues, wound infection) and surgical factors (inappropriate suture material, incorrect suture placement).

An incisional hernia usually starts as disruption of the musculofascial layers of a wound in the early postoperative period. Often the event passes unnoticed if the overlying skin wound has healed securely. Many incisional hernias may be preventable with the use of good surgical technique. The classic sign of wound disruption is a serosanguinous discharge.

Clinical features

These hernias commonly appear as a localised swelling involving a small portion of the scar but may present as a diffuse bulging of the whole length of the incision (Figure 60.27). There may be several discrete hernias along the length of the incision and unsuspected defects are often found at operation (Figure 60.28). Incisional hernias tend to increase steadily in size with time. The skin overlying large hernias may become thin and atrophic so that peristalsis may be seen in the underlying intestine. Vascular damage to skin may lead to dermatitis. Attacks of partial intestinal obstruction are common as there are usually coexisting internal adhesions. Strangulation is less frequent and most likely to occur when the fibrous defect is small and the sac is large. Most incisional hernias are broad-necked and carry a low risk of strangulation (Summary box 60.16).

Figure 60.27 A large multilocular incisional hernia.

Figure 60.28 Multiple defects seen during laparoscopic operation.

Summary box 60.16

Incisional hernia

- Incidence 10–50 per cent after surgery
- Causation due to patient, wound and surgeon factors
- Wide variation in size
- Often multiple defects within the same scar
- Obstruction is common but strangulation is rare
- Open and laparoscopic repairs possible

Treatment

Asymptomatic incisional hernias may not require treatment at all. The wearing of an abdominal binder or belt may prevent the hernia from increasing in size.

Principles of surgery

For the majority of incisional hernias, surgery is relatively straightforward and both open and laparoscopic options are available. A number of principles apply, irrespective of the technique used.

The repair should cover the whole length of the previous incision. Approximation of the musculofascial layers should be done with minimal tension and prosthetic mesh should be used

to reduce the risk of recurrence. Mesh may be contraindicated in a contaminated field, e.g. bowel injury during the dissection but, in a clean-contaminated field, such as after an elective bowel resection, mesh may be used if placed in a different anatomical plane to the contamination, such as in the extraperitoneal/retromuscular space. Appropriate systemic antibiotics should be used.

Open repair

Simple suture techniques without the use of prosthetic mesh for reinforcement, even with layered closure such as in Mayo, 'keel' or da Silva repairs, are not recommended today because of the high risk of recurrence. However, they may be the only option in the presence of gross contamination such as peritonitis.

The previous incision is opened along its full length to reveal any clinically unsuspected defects. The hernial sac, its neck and the margins of the defect are fully exposed. The sac can be opened, contents reduced, local adhesions divided and any redundant sac excised to allow safe reclosure of the peritoneum.

Mesh can be placed in one of several planes as for umbilical hernia repair. The simplest approach is an onlay mesh but increasingly the retromuscular sublay repair is preferred by expert surgeons and is described below.

Retromuscular sublay mesh repair

Vertical incisions are made through the fascia surrounding the rectus abdominus muscles so that the muscle can be separated and elevated from the posterior rectus sheath below. If possible, the medial edges of the posterior rectus sheath edges are sutured together with a continuous suture. In very large defects this may not be possible and below the arcuate line, the posterior sheath is deficient, being peritoneum and transversalis fascia only. In the case of transverse incision, where the defect extends lateral to the rectus sheath, internal oblique and transversus abdominis muscles form the posterior layer. A sheet of lightweight, large-pore prosthetic, elastic mesh is then laid between this posterior rectus sheath and belly(s) of the rectus muscle. It is fixed to the sheath by interrupted sutures. The mesh must be large enough to ensure 5 cm overlap of the underlying fascial defect in all directions. Careful haemostasis and meticulous asepsis are essential during this operation. The anterior rectus sheaths are then sutured together over the mesh so that, ideally, the mesh is completely covered by muscle and fascia and is not lying in the subcutaneous plane. Redundant skin may need to be excised. The risk of postoperative serous fluid collections is reduced by suction drainage.

Laparoscopic repair

Incisional hernias are increasingly being repaired by laparoscopic mesh techniques. Laparoscopy and division of adhesions is initially performed. Hernia contents are reduced and the fibrous margins of the hernia defect(s) are exposed. Often the falciform ligament and median umbilical fold need to be taken down. Some surgeons prefer to suture close the muscle defects first and then reinforce with mesh. Others simply fix the mesh under the defect with adequate overlap. The use of a tissue-separating mesh is essential. Various techniques have been described to size and then position the mesh accurately. The mesh is fixed to the abdominal wall by staples or transfascial sutures which pass through all muscle layers to hold the mesh.

In the presence of dense peritoneal adhesions, the laparoscopic surgeon needs to take great care as injury to bowel is

possible and may not be recognised. Diathermy is not used. If occult bowel injury does occur it can lead to postoperative peritonitis which is an extremely dangerous complication.

Management of the very large incisional hernia

Very large incisional hernias often require careful thought before treatment begins. If the volume of the sac is more than 25 per cent of the volume of the abdominal cavity (and this can be calculated from CT scan images) then there are likely to be issues of loss of abdominal domain when the hernia is repaired. The contents of the hernia, which have been outside the abdominal cavity for a long time, will not fit back inside, or if they do, it will result in high tension. High intra-abdominal pressure can lead to visceral compression and pulmonary complications due to impaired diaphragmatic movement. A tight abdomen can lead to wound breakdown and failure of the repair.

Techniques to overcome the potential loss of abdominal domain include preoperative abdominal expansion with progressive preoperative pneumoperitoneum over several weeks, resection of the omentum and/or colon at the time of repair, the use of prosthetic mesh to span the uncloseable gap in the musculofascial layer, or the use of musculofascial advancement or transposition flaps to achieve closure.

Even if loss of domain is not a concern, large defects can still be very difficult to close and the same special techniques may need to be used to avoid producing excessive tension in the repair. The Ramirez component separation technique, which incorporates relaxing incisions in the external oblique aponeurosis and/or the posterior sheath, is very useful as this enables either the anterior or posterior component of the rectus sheath to be drawn together. It may then be reinforced with a mesh.

Patients with poor quality or redundant skin may benefit from a wedge excision of skin and fat (lipectomy) to improve the abdominal contour postoperatively. Repair of these very large hernias is highly specialised surgery and is best done in specialist centres.

Reducing the risk of incisional hernia

The incidence of incisional hernia may be reduced by improving the patients' general condition preoperatively where possible – e.g. weight loss for obesity, or improving nutritional state for malnutrition. Closing the fascial layers with non-absorbable, or very slowly absorbable, sutures of adequate gauge is important. Traditional teaching was that sutures should be 1 cm deep and 1 cm apart. Recent work has shown that lower incisional hernia rates and reduced infection rates are gained when smaller and closer bites are used with a 2/0 suture rather than traditional heavier materials.

There is no evidence that interrupted sutures are better or worse than continuous. However, if continuous suturing is used, the tissue bites must not be too near the fascial edge nor pulled too tight or they may cut out. It has also been confirmed that the optimal ratio of suture length to wound length is 4:1 (Jenkins' rule). If less length than this is used, the suture bites are too far apart or too tight and the converse applies if more length than this is used.

Drains should be brought out through separate incisions and not through the wound itself as this leads to hernia formation.

Recent reports have suggested that placement of a prophylactic mesh in patients at high risk of hernia formation will substantially reduce that risk. This has been reported in obese

patients undergoing bariatric surgery and also to prevent parasomal herniation which occurs in up to 50 per cent of patients.

Spigelian hernia

These hernias are uncommon although are probably underdiagnosed. They affect men and women equally and can occur at any age, but are most common in the elderly. They arise through a defect in the Spigelian fascia which is the aponeurosis of the transversus abdominis muscle. Often these hernias advance through the internal oblique as well and spread out deep to the external oblique aponeurosis. The Spigelian fascia extends between the transversus muscle and the lateral border of the rectus sheath from the costal margin to the groin where it blends into the conjoint tendon. Most Spigelian hernias appear below the level of the umbilicus near the edge of the rectus sheath but they can be found anywhere along the 'Spigelian line' (Figure 60.29). There is a common misconception that they protrude below the arcuate line owing to deficiency of the posterior rectus sheath at that level, but in fact the defect is almost always above the arcuate line. In young patients they usually contain extraperitoneal fat only but in older patients there is often a peritoneal sac and they can become very large indeed.

They have also been described in infants and may be congenital, reflecting incomplete differentiation of the mesenchymal layers within the abdominal wall.

Clinical features

Young patients usually present with intermittent pain, due to pinching of the fat, similar to an epigastric hernia. A lump may or may not be palpable as the fatty hernia is small and the overlying external oblique is intact. Older patients generally present with a reducible swelling at the edge of the rectus sheath and may have symptoms of intermittent obstruction. The diagnosis should be suspected because of the location of the symptoms and is confirmed by CT. Ultrasound scanning has the advantage that it can be performed in the upright patient as no defect may be visible with the patient lying down.

Treatment

Surgery is recommended as the narrow and fibrous neck predisposes to strangulation. Surgery can be open or laparoscopic.

Figure 60.29 Spigelian hernia.

At open surgery a skin crease is made over the hernia, but no abnormality will be seen until the external oblique is opened. The sac and contents are dealt with and the small defect in the Spigelian fascia is repaired by suture or mesh laid deep to external oblique aponeurosis. The plane of the mesh can be extended medially into the posterior rectus sheath if required. The external oblique aponeurosis is closed over the mesh.

Laparoscopy is useful if no sac is palpable, but in young patients with a hernia only containing extraperitoneal fat, no hernia will be seen from within the peritoneum. In such cases, the peritoneum can be incised and the extraperitoneal plane explored for the small defect, which can then be closed either by suture or mesh. When an intraperitoneal sac is present, laparoscopic repair can be performed using either the intraperitoneal onlay of mesh (IPOM) or TAPP technique (Summary box 60.17).

Summary box 60.17

Spigelian hernia

- Rare
- Often misdiagnosed
- High risk of complications

Lumbar hernia

Most primary lumbar hernias occur through the inferior lumbar triangle of Petit bounded below by the crest of the ilium, laterally by the external oblique muscle and medially by the latissimus dorsi (Figure 60.30). Less commonly, the sac comes through the superior lumbar triangle, which is bounded by the 12th rib above, medially by the sacrospinalis and laterally by the posterior border of the internal oblique muscle. Primary lumbar hernias are rare, but may be mimicked by incisional hernias arising through flank incisions for renal operations or through incisions for bone grafts harvested from the iliac crest.

Differential diagnosis

A lumbar hernia must be distinguished from:

- a lipoma;
- a cold (tuberculous) abscess pointing to this position;
- pseudo-hernia due to local muscular paralysis. Lumbar pseudo-hernia can result from any interference with the nerve supply of the affected muscles, the most common cause being injury to the subcostal nerve during a renal operation.

Treatment

The natural history is for these hernias to increase in size and surgery is recommended. Lumbar hernias can be approached by open or laparoscopic surgery. The defects can be difficult to close with sutures and mesh is recommended.

The TAPP laparoscopic approach is gaining popularity. With the patient in a semilateral position ports are inserted well away from the defect. The peritoneum is incised above the hernia and dissected back to expose the muscle defect. The content, often extraperitoneal fat, is reduced and a mesh fixed with ample overlap. The peritoneum can then be resutured or tacked back to cover the mesh.

Lumbar incisional hernias can be approached in the same way but large ones, especially if there is a component of neuropathic

Figure 60.30 Inferior lumbar hernia, which contained caecum, appendix and small bowel. Note the filarial skin rash on the buttocks (courtesy of VJ Hartfield, formerly of SE Nigeria).

muscle atrophy causing a diffuse bulge (pseudo-hernia), can be very difficult and muscle-flap double-breasting with mesh reinforcement may be required.

Parastomal hernia

When surgeons create a stoma, such as a colostomy or ileostomy, they are effectively creating a hernia by bringing bowel out through the abdominal wall. The muscle defect created tends to increase in size over time and can ultimately lead to massive herniation around the stoma. The rate of parastomal hernia is over 50 per cent. For patients, it is very difficult to manage a stoma which is lying adjacent to or atop of a large hernia. Stoma appliance bags fit poorly leading to leakage.

The ideal surgical solution for the patient is to rejoin the bowel and remove the stoma altogether but this is not always possible. The stoma may be resited but further recurrence is likely. Various open suture and mesh techniques have been described to repair parastomal hernia but failure rates are high. Meshes are best placed in the retromuscular space. Laparoscopic repair is also possible using a large mesh with a central hole. It can be positioned around the bowel onto the parietal peritoneum.

Recent reports (Israelson) have described the use of prophylactic mesh insertion at the time of formation of the stoma. A lightweight, polypropylene mesh is inserted in the retromuscular space so that the bowel passes through a hole in the mesh centre. Using this technique, parastomal hernia rates have been reduced significantly.

Traumatic hernia

These hernias arise through non-anatomic defects caused by injury. They can be classified into three types:

- 1 Hernias through abdominal stab wound sites. These are effectively incisional hernias.

- 2 Hernias protruding through splits or tears in the abdominal muscles following blunt trauma.
- 3 Abdominal bulging secondary to muscle atrophy which occurs as a result of nerve injury or other traumatic denervation. Akin to the lumbar pseudo-hernia seen after open nephrectomy, these can arise following chest injury with damage to the intercostal nerves.

Clinical features

Traumatic hernias present as any other hernia. The key to the aetiology is in the history and the non-anatomic location of the hernia.

Treatment

Surgery may be justified if the hernia is sufficiently symptomatic, or if investigations suggest a narrow neck and hence a risk of obstruction or strangulation. Stab wound traumatic hernias are straightforward to repair using open or laparoscopic techniques as for other ventral hernias. Diffuse abdominal bulges are more difficult to correct and require some form of plication of the stretched musculofascial layer with mesh reinforcement to prevent further bulging in the future. Some bulging may persist however.

Rare external hernias

Perineal hernia

This type of hernia is very rare and includes:

- postoperative hernia through a perineal scar, which may occur after excision of the rectum;
- median sliding perineal hernia, which is a complete prolapse of the rectum;
- anterolateral perineal hernia, which occurs in women and presents as a swelling of the labium majus;
- posterolateral perineal hernia, which passes through the levator ani to enter the ischiorectal fossa.

Treatment

A combined abdominoperineal operation is generally the most satisfactory for the last two types of hernia. The hernia is exposed by an incision directly over it. The sac is opened and its contents are reduced. The sac is cleared from surrounding structures and the wound closed. With the patient in semi-Trendelenburg position, either laparoscopically or at open surgery, the abdomen is opened and the mouth of the sac is exposed. The sac is inverted, ligated and excised and the pelvic floor repaired by muscle apposition and, if indicated, buttressing of the repair with prosthetic mesh.

Obturator hernia

Obturator hernia, which passes through the obturator canal, occurs six times more frequently in women than in men. Most patients are over 60 years of age. The swelling is liable to be overlooked because it is covered by the pectineus. It seldom causes a definite swelling in Scarpa's triangle, but if the limb is flexed, abducted and rotated outwards, the hernia sometimes becomes apparent. The leg is usually kept in a semiflexed position and movement increases the pain. In more than 50 per cent of cases of strangulated obturator hernia, pain is referred along the obturator nerve by its geniculate branch to the knee. On vaginal or rectal examination the hernia can sometimes be

felt as a tender swelling in the region of the obturator foramen.

These hernias have often undergone strangulation, frequently of the Richter type, by the time of presentation.

Treatment

Operation is indicated. The diagnosis is rarely made preoperatively and so it is often approached through a laparotomy incision. Full Trendelenburg position is adopted. The constricting agent is the obturator fascia which can be stretched by inserting the operator's index finger, or suitable forceps, through the gap in the fascia. Content is reduced. If incision of the fascia is required, it is made parallel to the obturator vessels and nerve. The contents of the sac are dealt with in standard manner. The defect cannot be simply closed as one margin is bone and the obturator nerve and vessels run through it. It is best closed using a mesh plug. In the absence of mesh or in an infected field, the broad ligament can be used as a plug.

Laparoscopic TAPP repair may also be performed again using a mesh. To avoid nerve injury, glue can be used to fix a mesh over the defect.

Gluteal and sciatic hernias

Both of these hernias are very rare. A gluteal hernia passes through the greater sciatic foramen, either above or below the piriformis. A sciatic hernia passes through the lesser sciatic foramen. Differential diagnosis must be made between these conditions and:

- a lipoma or other soft tissue tumour beneath the gluteus maximus;
- a tuberculous abscess;
- a gluteal aneurysm.

All doubtful swellings in this situation can be characterised with CT scanning but, if in doubt, they should be explored by operation.

UMBILICAL CONDITIONS IN THE ADULT

Chronic infection

Chronic infection occurs in the umbilical area, particularly in patients with poor hygiene. It may also occur in the obese and when a paraumbilical hernia is present. It can be due to a plug of keratin causing chronic irritation. It is often encountered during elective surgery and may complicate the insertion of a laparoscope port at the umbilicus. A range of bacteria and fungi can be involved. Occasionally, a rapid onset, superficial cellulitis occurs even after minor surgery in this region. It is normally a streptococcus and treated with penicillin or other appropriate antibiotic. Pre-existing infection should be treated prior to surgery where possible.

Chronic fistula

Patients may present with a persistent discharge from the umbilical area. This may be due to simple, superficial infection or possibly an infected epidermoid cyst within the umbilicus. However, it may also be due to a fistulous connection to deeper structures.

In normal patients, the umbilicus is connected to the liver, bladder and gynaecological organs by various ligaments. Diseases of these organs, such as infection or malignancy, can extend

along these ligaments to appear at the umbilicus as a mass or fistulous discharge.

Chronic fistula may be a complication of umbilical hernia repair due to chronic infection of a mesh or around non-absorbable suture material. In most cases this problem arises soon after surgery but occasionally a chronic infection can occur months or even years after an operation. Antibiotics may help but most commonly the synthetic suture or mesh will need to be removed with a risk of recurrence of the hernia.

In fetal life the umbilicus was also connected to the gut by the vitellointestinal duct. In most patients this duct becomes totally obliterated and vanishes. The bowel end of the duct may persist as a Meckel's diverticulum. More rarely, the umbilical end persists leading to chronic discharge. If an abnormal connection between bowel and umbilicus persists then this band can act as a cause of adhesional intestinal obstruction.

Patent urachus

A connection between the urinary bladder and umbilicus usually presents in later life. This is due to increased pressure in the bladder as a result of obstruction from conditions such as prostatic hypertrophy. The cause of obstruction should be dealt with initially but if the problem persists then surgical excision of the patent urachus might be considered.

Malignancy at the umbilicus

Primary squamous carcinoma may occur. If tumour presents at the umbilicus it is most likely due to spread from internal organs along internal ligaments, for example from the liver along the falciform ligament. A malignant mass at the umbilicus is called a Sister Joseph's nodule. It usually indicates very advanced malignant disease and surgery probably has little to offer (Figure 60.31).

GENERAL INFECTION OF THE ABDOMINAL WALL

The skin of the abdominal wall, like all skin, is prone to develop superficial infection which may be spontaneous, due to minor trauma or to infection of skin lesions such as an epidermoid cyst. While antibiotics will suffice in most patients, if an abscess develops then surgical drainage may be required.

The close proximity of bowel and bowel organisms opens the abdominal wall to attack from a wide range of highly virulent bacteria. Most commonly, these are released during abdominal surgery such as appendicectomy and hence the need for appropriate antibiotic prophylactic cover.

Synergistic gangrene

This rare condition is due to the synergistic action of non-haemolytic streptococcus and staphylococcus causing rapid tissue necrosis and overwhelming systemic infection (Figure 60.32). It requires immediate administration of high-dose,

The neoplastic nodule sited at the umbilicus is known as **Sister Joseph's nodule**. Sister Mary Joseph made the observation that her patients with terminal cancer sometimes developed a red papular lesion in the umbilicus. She and William Mayo published this observation in 1928. However, it was Hamilton Bailey who coined the term 'Sister Mary Joseph's nodule' in 1949.

Sister Mary Joseph (nee Julia Dempsey), Nursing Superintendent, St Mary's Hospital, which became the Mayo Clinic, Rochester, MN, USA. The Mayo Clinic in Rochester, MN, USA, was founded in 1889 as the St Mary's Hospital by William Worrall Mayo and his two sons, William James Mayo and Charles Horace Mayo, both of whom became surgeons to the hospital.

Figure 60.31 Secondary nodule at the umbilicus – Sister Joseph's nodule.

broad-spectrum, powerful antibiotics in combination with early debridement of any non-viable tissue. Hyperbaric oxygen therapy has been advocated.

Other forms of severe abdominal wall infections occur, generally known as necrotising fasciitis (e.g. Fournier's gangrene). All of these conditions have a high associated morbidity and mortality. They occur in debilitated and immune-compromised patients but can occasionally occur in healthy patients. Rapid diagnosis and aggressive surgical debridement treatment is the key to success.

Cutaneous fistula

Due to the thickness of the abdominal wall, it is rare for abdominal inflammatory conditions to discharge spontaneously through the wall to the skin. Chronic intraperitoneal abscesses arising after occult bowel perforation, appendicitis, diverticulitis and cholecystitis are the most likely sources. CT scanning will locate the internal abscess and suggest the likely origin. Treatment today is usually by CT or ultrasound-guided drainage but the surgeon may be called on to remove the source organ, e.g. gall bladder.

Malignancy in its later stages can occasionally erode through the abdominal wall.

Figure 60.32 Bacterial synergistic gangrene of the chest and abdominal wall. The area has become gangrenous and looks like suede leather. Beware of amoebiasis cutis.

Crohn's disease also has a tendency to fistulate into adjacent organs and may develop an enterocutaneous fistula.

Abdominal compartment syndrome

Surgeons are increasingly aware of the harmful effect of high intra-abdominal pressures which can occur in severe intra-abdominal sepsis, such as pancreatitis and also aortic aneurysm rupture. High pressure leads to reduced blood flow and tissue ischaemia which contributes to multiorgan failure. While the abdominal wall has elasticity, if intra-abdominal volume increases due to fluid, gas, pus, tissue oedema, etc., then maximal capacity may be reached and pressure rises to a critical level. Tension releasing incisions, equivalent to a fasciotomy, have been suggested although this is not widely practised.

In some cases, after surgery for severe intraperitoneal sepsis, the surgeon cannot close the abdomen and may leave the incision wide open, covering abdominal contents with mesh or a saline-soaked dressing, planning to return at a future date to close the defect. This is called a laparostomy.

Neoplasms of the abdominal wall

As the abdominal wall is composed of muscle, fascia and bone, benign and malignant tumours can arise from each although these are rare.

Desmoid tumour

This is usually considered by pathologists to be a hamartoma and is more common in women. Some however believe it to be a fibroma and possibly the result of repeated trauma. Desmoids have been reported in familial adenomatous polyposis (FAP). Histologically they contain plasmoidal cell masses resembling giant cells. They undergo central myxomatous change. Surgical excision with a wide margin is required to prevent recurrence which is a frequent problem.

Fibrosarcoma

These tumours can occur anywhere in the body. They are generally highly malignant and respond poorly to both radio- and chemotherapy. Wide excision will often require plastic surgical reconstruction.

CHAPTER

61

The peritoneum, omentum, mesentery and retroperitoneal space

LEARNING OBJECTIVES

To recognise and understand:

- The causes and complications of localised and generalised peritonitis
- The clinical features of peritonitis and intraperitoneal abscess
- The principles of surgical management in patients with peritonitis and intraperitoneal abscess
- The causes and pathophysiology of ascites
- The pathophysiology and complications of adhesion formation
- The spectrum of mesenteric and retroperitoneal conditions

ANATOMY AND PHYSIOLOGY

Embryology

The peritoneal cavity, mesenteries and omentum have an anatomical complexity which can perhaps only be truly understood with surgical experience. Nevertheless, an understanding of the geometric alterations occurring during early gastrointestinal (GI) morphogenesis (regionalisation, elongation and coiling) of the derivatives of the endoderm (E = epithelium) and the visceral mesoderm (M = muscle and most of the rest) along with the later fusion of adjacent layers of peritoneum will give an appreciation of how the adult disposition is as it is.

Adult arrangement and functions

The peritoneal cavity is the largest cavity in the body, the surface area of its lining membrane (2 m² in an adult) being nearly equal to that of the skin. The peritoneal membrane is composed of flattened polyhedral cells (mesothelium), one layer thick, resting upon a thin layer of fibroelastic tissue. This membrane is conveniently divided into two parts – the visceral peritoneum surrounding the viscera and the parietal peritoneum lining the other surfaces of the cavity. Beneath the peritoneum, supported by a small amount of areolar tissue, lies a network of lymphatic vessels and rich plexuses of capillary blood vessels from which all absorption and exudation must occur. In health, only a few millilitres of peritoneal fluid is found in the peritoneal cavity. The fluid is pale yellow, somewhat viscid and contains lymphocytes and other leukocytes; it lubricates the viscera, allowing easy movement and peristalsis. The parietal portion is richly supplied with nerves and, when irritated, causes severe pain that is accurately localised to the affected area. The visceral peritoneum, in contrast, is poorly supplied with nerves (these being

situated around blood vessels) and its irritation causes pain that is usually poorly localised to the midline.

The peritoneum has a number of functions (Summary box 61.1).

The peritoneum has the capacity to absorb large volumes of fluid: this ability is used during peritoneal dialysis in the treatment of renal failure. However, the peritoneum can also produce large volumes of fluid (ascites) and an inflammatory exudate when injured (peritonitis). During expiration, intra-abdominal pressure is reduced and peritoneal fluid, aided by capillary attraction, travels in an upward direction towards the diaphragm. Experimental evidence shows that particulate matter and bacteria are absorbed within a few minutes into the lymphatic network through a number of 'pores' within the diaphragmatic peritoneum. The circulation of peritoneal fluids may be responsible for the occurrence of abscesses distant from primary disease. When parietal peritoneal defects are created, healing occurs not from the edges but by the development of new mesothelial cells throughout the surface of the defect. In this way, large defects heal as rapidly as small defects.

Summary box 61.1

Functions of the peritoneum

- In health
 - Visceral lubrication
 - Fluid and particulate absorption
- In disease
 - Pain perception (mainly parietal)
 - Inflammatory and immune responses
 - Fibrinolytic activity

SCOPE OF DISEASE

The peritoneum, mesentery and omentum may be the site of a variety of conditions that reflect their relationship to other anatomical structures or in some instances their primary functions (Summary box 61.2).

Summary box 61.2

Scope of disease

Intraperitoneal disease

- Peritonitis
 - Primary
 - Secondary
- Abscess
- Ascites
 - Transudate
 - Exudate
- Tumours
 - Primary
 - Secondary
- Adhesions

Omental disease

- Hernia
- Adhesions
- Torsion
- Neoplasia

Mesenteric disease

- Trauma
- Ischaemia
- Inflammation
- Cysts
- Neoplasia

Retroperitoneal disease

- Chronic inflammation/fibrosis
- Abscess
- Tumours

Summary box 61.3

Causes of peritoneal inflammation

- Bacterial, gastrointestinal and non-gastrointestinal
- Chemical, e.g. bile, barium
- Allergic, e.g. starch peritonitis
- Traumatic, e.g. operative handling
- Ischaemia, e.g. strangulated bowel, vascular occlusion
- Miscellaneous, e.g. familial Mediterranean fever

Although acute bacterial peritonitis most commonly arises from a perforation of a viscus of the alimentary tract, other routes of infection can include the female genital tract and exogenous contamination. There are also less common forms in which the aetiology is a primary 'spontaneous' peritonitis, in which a pure infection with streptococcal, pneumococcal or haemophilus bacteria occurs. Summary box 61.4 outlines the main causes of bacterial peritonitis.

Summary box 61.4

Paths to peritoneal infection

- Gastrointestinal perforation, e.g. perforated ulcer, appendix, diverticulum
- Transmural translocation (no perforation), e.g. pancreatitis, ischaemic bowel
- Exogenous contamination, e.g. drains, open surgery, trauma
- Female genital tract infection, e.g. pelvic inflammatory disease
- Haematogenous spread (rare), e.g. septicaemia

PERITONITIS

Peritonitis is simply defined as inflammation of the peritoneum and may be localized or generalised. Most cases of peritonitis are caused by an invasion of the peritoneal cavity by bacteria, so that when the term 'peritonitis' is used without qualification, acute bacterial peritonitis is often implied. In this instance, free fluid spills into the peritoneal cavity and circulates largely directed by the normal peritoneal attachments and gravity. For example, spillage from a perforated peptic ulcer may run down the right paracolic gutter leading to presentation with pain in the right iliac fossa (Valentino's syndrome). Even in patients with non-bacterial peritonitis (e.g. acute pancreatitis, intraperitoneal rupture of the bladder or haemoperitoneum), the peritoneum often becomes infected by transmural spread of organisms from the bowel. Such translocation is a feature of the systemic inflammatory response on the bowel and it is not long (often a matter of hours) before a bacterial peritonitis develops. Most duodenal and gastric perforations are initially sterile for up to several hours before becoming secondarily infected. Other causes of peritoneal inflammation are shown in Summary box 61.3.

Microbiology

Bacteria from the gastrointestinal tract

The number of bacteria within the lumen of the gastrointestinal tract is normally low until the distal small bowel is reached. However, disease leading to stasis and overgrowth (e.g. obstruction, chronic and acute motility disturbances) may increase proximal colonisation. The biliary and pancreatic tracts are also normally free from bacteria, although they may be infected in disease, e.g. gallstones. Peritoneal infection is usually caused by two or more bacterial strains. Gram-negative bacteria contain endotoxins (lipopolysaccharides) in their cell walls that have multiple toxic effects on the host, primarily by causing the release of tumour necrosis factor (TNF) from host leukocytes. Systemic absorption of endotoxin may produce endotoxic shock with hypotension and impaired tissue perfusion. Other bacteria such as *Clostridium welchii* produce harmful exotoxins. Bacteroides are commonly found in peritonitis. These Gram-negative, non-spore-forming organisms, although predominant in the lower intestine, often escape detection because they are strictly anaerobic and slow to grow on culture media unless there is an adequate carbon dioxide tension in the anaerobic apparatus. In many laboratories, the culture is discarded if there is no growth in 48 hours. These organisms are resistant to penicillin and streptomycin but sensitive to metronidazole, clindamycin,

Rudolph Valentino, Italian actor died during surgery for this in New York in 1926, aged 31 years.

William Henry Welch, 1850–1934, Professor of Pathology, Johns Hopkins University, Baltimore, MD, USA, discovered the causative organism of gas gangrene in 1892.

William Alexander Gillespie, formerly Professor of Clinical Bacteriology, the University of Bristol, Bristol, UK.

lincomycin and cephalosporin compounds. Since the widespread use of metronidazole (Flagyl), *Bacteroides* infections have greatly diminished.

Non-gastrointestinal causes of peritonitis

Pelvic infection via the Fallopian tubes is responsible for a high proportion of 'non-gastrointestinal' infections. The most common offending organisms are chlamydia and gonococcus. These organisms lead to a thinning of cervical mucus and allow bacteria from the vagina into the uterus and oviducts, causing infection and inflammation. A variant of transperitoneal spread of such organisms is perihepatitis which can cause scar tissue to form on Glisson's capsule, a thin layer of connective tissue surrounding the liver (Fitz-Hugh–Curtis syndrome). Other bacterial variants that are discussed separately include tuberculosis and other mycobacterial strains and those causing primary peritonitis (pneumococcus, staphylococcus and streptococcus spp). Fungal peritonitis is uncommon but may complicate severely ill patients (Summary box 61.5).

Summary box 61.5

Microorganisms in peritonitis

Gastrointestinal source

- *Klebsiella pneumoniae*

Other sources

- *Chlamydia trachomatis*
- *Neisseria gonorrhoeae*
- *Haemolytic streptococci*
- *Staphylococcus*
- *Streptococcus pneumoniae*
- *Mycobacterium tuberculosis* and other spp.
- Fungal infections

Localised peritonitis

Anatomical and pathological factors may favour the localisation of peritonitis.

Anatomical

The greater sac of the peritoneum is divided into (1) the subphrenic spaces, (2) the pelvis and (3) the peritoneal cavity proper. The last is divided into a supracolic and an infracolic compartment by the transverse colon and transverse mesocolon, which deters the spread of infection from one to the other. When the supracolic compartment overflows, as is often the case when a peptic ulcer perforates, it does so over the colon into the infracolic compartment or by way of the right paracolic gutter to the right iliac fossa and hence to the pelvis.

Pathological

The clinical course is determined in part by the manner in

which adhesions form around the affected organ. Inflamed peritoneum loses its glistening appearance and becomes reddened and velvety. Flakes of fibrin appear and cause loops of intestine to become adherent to one another and to the parietes. There is an outpouring of serous inflammatory exudate rich in leukocytes and plasma proteins that soon becomes turbid; if localisation occurs, the turbid fluid becomes frank pus. Peristalsis is retarded in affected bowel and this helps to prevent distribution of the infection. The greater omentum, by enveloping and becoming adherent to inflamed structures, often forms a substantial barrier to the spread of infection (see below).

Diffuse (generalised) peritonitis

A number of factors may favour the development of diffuse peritonitis:

- Speed of peritoneal contamination is a prime factor. If an inflamed appendix or other hollow viscus perforates before localisation has taken place, there will be an efflux of contents into the peritoneal cavity, which may spread over a large area almost instantaneously. Perforation proximal to an obstruction or from sudden anastomotic separation is associated with severe generalised peritonitis and a high mortality rate.
- Stimulation of peristalsis by the ingestion of food or even water hinders localisation. Violent peristalsis occasioned by the administration of a purgative or an enema may cause the widespread distribution of an infection that would otherwise have remained localised.
- The virulence of the infecting organism may be so great as to render the localisation of infection difficult or impossible.
- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance ('immune deficiency') may result from use of drugs (e.g. steroids), disease (e.g. acquired immune deficiency syndrome (AIDS)) or old age.

With appropriate treatment, localised peritonitis usually resolves; in about 20 per cent of cases, an abscess follows. Infrequently, localised peritonitis becomes diffuse. Conversely, in favourable circumstances, diffuse peritonitis can become localised, most frequently in the pelvis or at multiple sites within the abdominal cavity.

Clinical features

Localised peritonitis

The initial symptoms and signs of localised peritonitis are those of the underlying condition – usually visceral inflammation (hence abdominal pain, specific GI symptoms + malaise, anorexia and nausea). When the peritoneum becomes inflamed, abdominal pain will worsen and, in general, temperature and pulse rate will rise. The pathognomonic signs are localised guarding (involuntary abdominal wall contraction to protect the viscus from the examining hand), a positive 'release' sign (rebound tenderness) and, sometimes, rigidity (involuntary constant contraction of the abdominal wall over the inflamed parietes). If inflammation arises under the diaphragm, shoulder tip ('phrenic') pain may be felt as the pain is referred to the C5 dermatome. In cases of pelvic peritonitis arising from an inflamed

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, The Czech Republic; Zurich, Switzerland; and The Rush Medical College, Chicago, IL, USA.

appendix in the pelvic position or from salpingitis, the abdominal signs are often slight; there may be deep tenderness of one or both lower quadrants alone, but a rectal or vaginal examination reveals marked tenderness of the pelvic peritoneum.

Diffuse (generalised) peritonitis

Early

Abdominal pain is severe and made worse by moving or breathing. It is first experienced at the site of the original lesion and spreads outwards from this point. The patient usually lies still. Tenderness and generalised guarding are found on palpation when the peritonitis affects the anterior abdominal wall. Infrequent bowel sounds may still be heard for a few hours but they cease with the onset of paralytic ileus. Pulse and temperature rise in accord with degree of inflammation and infection.

Late

If resolution or localisation of generalised peritonitis does not occur, the abdomen will become rigid (generalised rigidity). Distension is common and bowel sounds are absent. Circulatory failure ensues, with cold, clammy extremities, sunken eyes, dry tongue, thready (irregular) pulse and drawn and anxious face (Hippocratic facies; Figure 61.1). The patient finally lapses into unconsciousness. With early diagnosis and adequate treatment, this condition is rarely seen in modern surgical practice (Summary box 61.6).

Summary box 61.6

Clinical features of peritonitis

- Abdominal pain, worse on movement, coughing and deep respiration
- Constitutional upset: anorexia, malaise, fever, lassitude
- GI upset: nausea ± vomiting
- Pyrexia (may be absent)
- Raised pulse rate
- Tenderness ± guarding/rigidity/rebound of abdominal wall
- Pain/tenderness on rectal/vaginal examination (pelvic peritonitis)
- Absent or reduced bowel sounds
- 'Septic shock' (systemic inflammatory response syndrome (SIRS) and multiorgan dysfunction syndrome (MODS)) in later stages

Diagnostic aids

Investigations may elucidate a doubtful diagnosis, but the importance of a careful history and repeated examination must not be forgotten.

Bedside

- Urine dipstick for urinary tract infection
- ECG if diagnostic doubt (as to cause of abdominal pain) or cardiac history.

Bloods

- Baseline U&E for treatment
- Full blood count for white cell count (WCC)
- Serum amylase estimation may establish the diagnosis of acute

Figure 61.1 The Hippocratic facies in terminal diffuse peritonitis.

pancreatitis provided that it is remembered that moderately raised values are frequently found following other abdominal catastrophes and operations, e.g. perforated duodenal ulcer

- Group and save serum may be taken as an adjunct to impending surgery.

Imaging

- Erect chest radiograph to demonstrate free subdiaphragmatic gas (Figure 61.2a).
- A supine radiograph of the abdomen may confirm the presence of dilated gas-filled loops of bowel (consistent with a paralytic ileus), occasionally show other gas-filled structures that may aid diagnosis, e.g. biliary tree; the faecal pattern may act as a guide to colonic disease (absent in sites of significant inflammation, e.g. diverticulitis). In the patient who is too ill for an 'erect' film, a lateral decubitus film can show gas beneath the abdominal wall (if CT unavailable).
- Multiplanar computed tomography (CT) is increasingly used to identify the cause of peritonitis (Figures 61.2b and 61.3) and may also influence management decisions, e.g. surgical strategy. There is an abundance of recent published evidence to support its use in managing acute abdominal pain.
- Ultrasound scanning has undoubted value in certain situations such as pelvic peritonitis in females and localised right upper quadrant peritonism.

Invasive

- In the era of access to high quality CT scanning, peritoneal diagnostic aspiration has little residual value.

Management

General care of the patient

The care of critically ill surgical patients is described in detail in Chapters 14, 17 and 21. Nutritional support is covered in Chapter 18 and anaesthesia and pain relief in Chapter 15. Depending on degree (localised/generalised), duration and severity, patients will require some or all of the following.

Figure 61.2 (a) Gas under the diaphragm in a patient with free perforation and peritonitis; (b) representative computed tomography axial image through the pelvis of the same patient showing perforated sigmoid diverticular disease.

Correction of fluid loss and circulating volume

Patients are frequently hypovolaemic with electrolyte disturbances. The plasma volume must be restored and electrolyte concentrations corrected. Fluid balance should be monitored and pre-existent and ongoing losses corrected. Special measures may be needed for cardiac, pulmonary and renal support, especially if septic shock is present (see Chapter 2), including central venous pressure monitoring in patients with concurrent disease.

Urinary catheterisation ± gastrointestinal decompression

A urinary catheter will give a guide to central perfusion and will be required if abdominal surgery is to proceed. A nasogastric tube is commonly passed to allow drainage ± aspiration until paralytic ileus has resolved.

Antibiotic therapy

Administration of parenteral broad-spectrum (aerobic and anaerobic) antibiotics prevents the multiplication of bacteria and the release of endotoxins.

Figure 61.3 Acute pancreatitis seen on computed tomography scanning with swelling of the gland and surrounding inflammatory changes (courtesy of Dr J Healy, Chelsea and Westminster Hospital, London, UK).

Analgesia

The patient should be nursed in the sitting-up position and must be relieved of pain before and after operation. If appropriate expertise is available, epidural infusion may provide excellent analgesia. Freedom from pain allows early mobilisation and adequate physiotherapy in the postoperative period, which helps to prevent basal pulmonary collapse, deep-vein thrombosis and pulmonary embolism.

Specific treatment of the cause

While difficult to generalise, in patients where specific treatment has not been guided by CT scanning, early surgical intervention is to be preferred to a 'wait and see' policy assuming that the patient is fit for anaesthesia and that resuscitation has resulted in a satisfactory restitution of normal body physiology. This rule is particularly true for previously healthy patients and those with postoperative peritonitis. More caution is, of course, required in patients at high operative risk because of comorbidity or advanced age.

In those patients with a preoperative diagnosis, if the cause of peritonitis is amenable to surgery, operation must be carried out as soon as the patient is fit. This is usually within a few hours. In peritonitis caused by pancreatitis or salpingitis, or in cases of primary peritonitis of streptococcal or pneumococcal origin, non-operative treatment is preferred provided the diagnosis can be made with confidence. It is beyond the remit of this chapter to cover specific causes of peritonitis and their treatment, be it by open or laparoscopic approach. However, in general, surgery is directed to removing (or diverting) the cause and subsequent adequate peritoneal lavage ± drainage. In operations for generalised peritonitis it is essential that, after the cause has been dealt with, the whole peritoneal cavity is explored with the sucker and, if necessary, mopped dry until all seropurulent exudate is removed. The use of a large volume of saline (typically 3 litres) containing dissolved antiseptic or antibiotic has been shown to be effective (Summary box 61.7).

Prognosis and complications

With modern treatment, diffuse peritonitis carries a mortality rate of about 10 per cent reflecting the degree and duration of peritoneal contamination, age and fitness of the patient and the

 - Residual or recurrent abscess/inflammatory mass
 - Portal pyaemia/liver abscess
 - Adhesional small bowel obstruction

SPECIAL FORMS OF PERITONITIS**Bile peritonitis**

Unless there is reason to suspect that the biliary tract was damaged during operation or the patient has proven acute cholecystitis, it is improbable that bile as a cause of peritonitis will be thought of until the abdomen has been opened. The common causes of bile peritonitis are shown in Summary box 61.9.

Unless the bile has extravasated slowly and the collection becomes shut off from the general peritoneal cavity, there are symptoms (often severe pain) and signs of diffuse peritonitis. After a few hours a tinge of jaundice is not unusual. Laparotomy (or laparoscopy) should be undertaken with evacuation of the bile and peritoneal lavage. The source of bile leakage should be identified and treated accordingly. Infected bile is more lethal than sterile bile. A 'blown' duodenal stump should be drained as it is too oedematous to repair, but sometimes it can be covered by a jejunal patch. The patient is often jaundiced from absorption of peritoneal bile, but the surgeon must ensure that the abdomen is not closed until any obstruction to a major bile duct has been either excluded or relieved. Bile leaks after cholecystectomy or liver trauma may be dealt with by percutaneous (ultrasound-guided) drainage and endoscopic biliary stenting to reduce bile duct pressure. The drain is removed when dry and the stent at 4–6 weeks.

Summary box 61.9**Causes of bile peritonitis**

- Perforated cholecystitis
- Postcholecystectomy
 - Cystic duct stump leakage
 - Leakage from an accessory duct in the gall bladder bed
 - Bile duct injury
 - T-tube drain dislodgement (or tract rupture on removal)
- Following other operations/procedures
 - Leaking duodenal stump postgastrectomy
 - Leaking biliary–enteric anastomosis
 - Leakage around percutaneous placed biliary drains
- Following liver trauma

Primary peritonitis

Primary pneumococcal peritonitis may complicate nephrotic syndrome or cirrhosis in children. Otherwise healthy children, particularly girls between three and nine years of age, may also be affected, and it is likely that the route of infection is sometimes via the vagina and Fallopian tubes. At other times, and always in males, the infection is blood-borne and secondary to respiratory tract or middle ear disease. The prevalence of pneumococcal peritonitis has declined greatly and the condition is now rare.

Clinical features

The onset is sudden and the earliest symptom is pain localised to the lower half of the abdomen. The temperature is raised to 39°C or more and there is usually frequent vomiting. After 24–48 hours, profuse diarrhoea is characteristic. There is usually increased frequency of micturition. The last two symptoms are caused by severe pelvic peritonitis. On examination, peritonism is usually diffuse but less prominent than in most cases of a perforated viscus leading to peritonitis.

Investigation and treatment

A leukocytosis $\geq 30\,000\ \mu\text{L}$ with approximately 90 per cent polymorphs suggests pneumococcal peritonitis rather than another cause, e.g. appendicitis. After starting antibiotic therapy and correcting dehydration and electrolyte imbalance, early surgery is required unless spontaneous infection of pre-existing ascites is strongly suspected, in which case a diagnostic peritoneal tap is useful. Laparotomy or laparoscopy may be used. Should the exudate be odourless and sticky, the diagnosis of pneumococcal peritonitis is practically certain, but it is essential to perform a careful exploration to exclude other pathology. Assuming that no other cause for the peritonitis is discovered, some of the exudate is aspirated and sent to the laboratory for microscopy, culture and sensitivity tests. Thorough peritoneal lavage is carried out and the incision closed. Antibiotic and fluid replacement therapy are continued and recovery is usual.

Other organisms are now known to cause some cases of primary peritonitis in children, including *Haemophilus*, other streptococci and a few Gram-negative bacteria. Underlying pathology (including an intravaginal foreign body in girls) must always be excluded before primary peritonitis can be diagnosed with certainty. Idiopathic streptococcal and staphylococcal peritonitis can also occur in adults.

Tuberculous peritonitis

Intra-abdominal tuberculosis is very common in the developing world where all general surgeons are familiar with its presentation and management. The incidence is however also rising in areas of the developed world as a consequence of migration and immunosuppression where *Mycobacterium avium-intracellulare* is becoming increasingly prevalent with the widespread increase in human immunodeficiency virus (HIV) coinfection. Abdominal tuberculosis (TB) includes intraperitoneal, GI tract and solid organ disease forms with TB peritonitis being a common site-specific variant. Although still uncommon, TB peritonitis requires some specific mention since it is often diagnosed late in the course of the disease, resulting in undue patient morbidity and mortality.

Tuberculosis can spread to the peritoneum through the GI tract (typically ileocaecal region) via mesenteric lymph nodes or directly from the blood, usually from the 'miliary' (Figure 61.4a) but occasionally the 'cavitating' form of pulmonary TB, lymph and the Fallopian tubes; 50–83 per cent of patients with abdominal TB can be expected to have peritoneal involvement. Clinical or subclinical ascites is reported in virtually all patients with TB peritonitis and is frequently a presenting feature. In the most common form of the disease, wet-type peritonitis, ascites may be localised or generalised throughout the peritoneal cavity. Multiple tubercle deposits appear on both layers of the peritoneum. Diagnosis is via abdominal ultrasound or CT to detect ascites and lymphadenopathy \pm diffuse thickening of the peritoneum, mesentery and/or omentum (Figure 61.4b). Ascitic fluid is typically a straw-coloured exudate (protein >25 – 30 g/L) with white cells >500 mm³ and lymphocytes >40 per cent.

Unfortunately, diagnostic smears for acid-fast bacilli are diagnostic in <3 per cent of patients and culture may take up to 4–8 weeks with no guarantee of a positive result. Laparoscopy and peritoneal biopsy may thus be helpful to couple typical appearances with histology. Management is principally supportive (nutrition and hydration) and medical (systemic antituberculous therapy) although surgery may be required for specific complications such as intestinal obstruction.

The main features are summarized in Summary box 61.10.

Summary box 61.10

Tuberculous peritonitis

- Acute (may be clinically indistinguishable from acute bacterial peritonitis) and chronic forms
- Abdominal pain, sweats, malaise and weight loss are frequent
- Ascites common, may be loculated
- Caseating peritoneal nodules are common – distinguish from metastatic carcinoma and fat necrosis of pancreatitis
- Intestinal obstruction may respond to antituberculous treatment without surgery

Familial Mediterranean fever (periodic peritonitis)

Familial Mediterranean fever (periodic peritonitis) is characterised by abdominal pain and tenderness, mild pyrexia, polymorphonuclear leukocytosis and, occasionally, pain in the

Figure 61.4 (a) Chest computed tomography from a 55-year-old man showing miliary tuberculosis; (b and c) representative computed tomography images from the same patient showing gross ascites, nodular stranding in the omentum and mesentery as well as nodular enhancement of the peritoneum – tuberculous peritonitis (courtesy of Dr S Burke, Homerton University Foundation Trust, London, UK).

thorax and joints. The duration of an attack is 24–72 hours, when it is followed by complete remission, but exacerbations recur at regular intervals. Most of the patients have undergone appendectomy in childhood. This disease, often familial, is limited principally to Arab, Armenian and Jewish populations; other races are occasionally affected. Mutations in the *MEFV* (Mediterranean fever) gene appear to cause the disease. This gene produces a protein called pyrin, which is expressed mostly in neutrophils but whose exact function is not known.

Usually, children are affected but it is not rare for the disease to make its first appearance in early adult life, with cases in women outnumbering those in men by two to one. Exceptionally, the disease becomes manifest in patients over 40 years of age. At operation, which may be necessary to exclude other causes (but should be avoided if possible), the peritoneum is inflamed, particularly in the vicinity of the spleen and the gall bladder. There is no evidence that the interior of these organs is abnormal. Colchicine therapy is used during attacks and to prevent recurrent attacks.

INTRAPERITONEAL ABSCESS

Following intraperitoneal sepsis (usually manifest first as local or diffuse peritonitis), the anatomy of the peritoneal cavity is such that with the influence of gravity (depending on patient position – sitting or supine), abscess development usually occupies one of a number of specific abdominal or pelvic sites (Figure 61.5).

In general, the symptoms and signs of a purulent collection may be vague and consist of nothing more than lassitude, anorexia and malaise; pyrexia (often low-grade), mild tachycardia and localised tenderness. Certain sites have more specific clinical features (Summary box 61.11). Larger abscesses will give rise to the picture of swinging pyrexia and pulse and a palpable mass. Blood tests will reveal elevated inflammatory markers.

Summary box 61.11

Clinical features of an abdominal/pelvic abscess

Symptoms

- Malaise, lethargy – failure to recover from surgery as expected
- Anorexia and weight loss
- Sweats ± rigors
- Abdominal/pelvic pain
- Symptoms from local irritation, e.g. shoulder tip/hiccoughs (subphrenic), diarrhoea and mucus (pelvic), nausea and vomiting (any upper abdominal)

Signs

- Increased temperature and pulse ± swinging pyrexia
- Localised abdominal tenderness ± mass (including on pelvic exam)

Pelvic abscess

The pelvis is the most common site of abscess formation because the vermiform appendix is often pelvic in position and the Fallopian tubes are also frequent sites of infection. A

Figure 61.5 Common situations for residual abscesses: (1) subphrenic; (2) paracolic; (3) right iliac fossa; (4) pelvic.

pelvic abscess can also occur as a sequel to any case of diffuse peritonitis and is common after anastomotic leakage following colorectal surgery.

Clinical features

The most characteristic symptoms are of pelvic pain, diarrhoea and the passage of mucus in the stools. Rectal examination reveals a bulging of the anterior rectal wall, which, when the abscess is ripe, becomes softly cystic.

Investigation and management

Left to nature, a proportion of these abscesses burst into the rectum, after which the patient nearly always recovers rapidly. If this does not occur, the abscess should be drained deliberately. In women, vaginal drainage through the posterior fornix is often chosen. In other cases, when the abscess is definitely pointing into the rectum, rectal drainage (Figure 61.6) is employed. If any uncertainty exists, the presence of pus should be confirmed by ultrasound or CT scanning (Figure 61.7). Laparotomy is almost never necessary and rectal drainage of a pelvic abscess is far preferable to suprapubic drainage, which risks exposing the general peritoneal cavity to infection. Drainage tubes can also be inserted percutaneously or via the vagina or rectum under ultrasound or CT guidance.

Figure 61.6 Opening a pelvic abscess into the rectum.

Figure 61.7 A pelvic abscess seen on computed tomography scanning (courtesy of Dr J Healy, Chelsea and Westminster Hospital, London, UK).

Intraperitoneal abscess

Anatomy

The complicated arrangement of the peritoneum results in the formation of four intraperitoneal spaces in which pus may commonly collect (Figure 61.8).

Left subphrenic space

This is bounded above by the diaphragm and behind by the left triangular ligament and the left lobe of the liver, the gastrohepatic omentum and the anterior surface of the stomach. To the right is the falciform ligament and to the left the spleen, gastrosplenic omentum and diaphragm. The common cause of an abscess here is an operation on the stomach, the tail of the pancreas, the spleen or the splenic flexure of the colon.

Left subhepatic space/lesser sac

The most common cause of infection here is complicated acute pancreatitis. In practice, a perforated gastric ulcer rarely causes a collection here because the potential space is obliterated by adhesions.

Right subphrenic space

This space lies between the right lobe of the liver and the diaphragm. It is limited posteriorly by the anterior layer of the coronary and the right triangular ligaments and to the left by the falciform ligament. Common causes of abscess here are perforating cholecystitis, a perforated duodenal ulcer, a duodenal cap 'blow-out' following gastrectomy and appendicitis.

Right subhepatic space

This lies transversely beneath the right lobe of the liver in Rutherford Morison's pouch. It is bounded on the right by the right lobe of the liver and the diaphragm. To the left is situated the foramen of Winslow and below this lies the duodenum. In front are the liver and the gall bladder and behind are the upper part of the right kidney and the diaphragm. The space is

Figure 61.8 (a) Intraperitoneal abscesses on transverse section: (1) the left subphrenic space, (2) left subhepatic space/lesser sac, (3) right subphrenic space, (4) right subhepatic space. (b) Intraperitoneal abscesses on sagittal section: (1) left subphrenic, (2) left subhepatic/lesser sac, (3) right subphrenic, (4) right subhepatic.

bounded above by the liver and below by the transverse colon and hepatic flexure. It is the deepest space of the four and the most common site of a subphrenic abscess, which usually arises from appendicitis, cholecystitis, a perforated duodenal ulcer or following upper abdominal surgery.

Clinical features

The symptoms and signs of subphrenic infection are frequently non-specific and it is well to remember the aphorism, 'pus somewhere, pus nowhere, pus under the diaphragm'. A common history is that, when some infective focus in the abdominal cavity has been dealt with, the condition of the patient improves temporarily but, after an interval of a few days or weeks, symptoms of toxæmia reappear. The condition of the patient steadily, and often rapidly, deteriorates. Sweating, wasting and anorexia are present. There is sometimes epigastric fullness and pain, or pain in the shoulder on the affected side due to irritation of sensory fibres in the phrenic nerve, this being referred along the descending branches of the cervical plexus. Persistent hiccoughs may be a presenting symptom. A swinging pyrexia is usually present. If the abscess is anterior, abdominal examination will reveal some tenderness, rigidity or even a palpable swelling. Sometimes the liver is displaced downwards but more often it is fixed by adhesions.

Investigation and management

Examination of the chest and plain radiograph are important, as in the majority of cases, collapse of the lung or evidence of basal effusion or even an empyema are evident. The modern management of an abscess is by radiological diagnosis using ultrasound or CT guidance (Figure 61.9) followed by drainage. The same tube can be used to instill antibiotic solutions or irrigate the

Figure 61.9 A subphrenic abscess drained under computed tomography guidance (courtesy of Dr J Healy, Chelsea and Westminster Hospital, London, UK).

abscess cavity if necessary. In some instances, monitoring may be appropriate by either clinically marking out limits on the abdominal wall (if palpable) with daily examination. However, more commonly, repeat ultrasound or CT scanning will be required. Radiolabelled white cell scanning may occasionally prove helpful when other imaging techniques have failed. In most cases, with the aid of percutaneous drainage and antibiotic treatment, the abscess or mass gradually reduces in size until, finally, it is undetectable. Open drainage of an intraperitoneal collection is thus now uncommon but may be necessary. If a swelling can be detected in the subcostal region or in the loin, an incision is made over the site of maximum tenderness or over any area where oedema or redness is discovered. Cautious blunt finger exploration can then be used to avoid dissemination of pus into the peritoneal or pleural cavities and minimise the risk of an intestinal fistula. When the cavity is reached, all of the fibrinous loculi must be broken down with the finger and one or two drainage tubes fully inserted. These drains are withdrawn gradually during the next 10 days and the closure of the cavity can be checked by sinograms or scanning. Appropriate antibiotics are also given.

ASCITES

Ascites is defined as an accumulation of excess serous fluid within the peritoneal cavity.

Pathophysiology

The balanced effects of plasma and peritoneal colloid osmotic and hydrostatic pressures determine the exchange of fluid between the capillaries and the peritoneal fluid. Protein-rich fluid enters the peritoneal cavity when capillary permeability is increased, as in peritonitis and carcinomatosis peritonei. Capillary pressure may be increased because of generalised water retention, cardiac failure, constrictive pericarditis or vena cava obstruction. Capillary pressure is raised selectively in the portal venous system in the Budd–Chiari syndrome, cirrhosis of the liver or extrahepatic portal venous obstruction. Plasma colloid osmotic pressure may be lowered in patients with reduced nutritional intake, diminished intestinal absorption, abnormal

protein losses or defective protein synthesis such as occurs in cirrhosis. Peritoneal lymphatic drainage may be impaired, resulting in the accumulation of protein-rich fluid. A list of causes of ascites is given in Summary box 61.12.

Summary box 61.12

Causes of ascites

Transudates (protein <25 g/L)

- Low plasma protein concentrations
 - Malnutrition
 - Nephrotic syndrome
 - Protein-losing enteropathy
- High central venous pressure
 - Congestive cardiac failure
- Portal hypertension
 - Portal vein thrombosis
 - Cirrhosis

Exudates (protein >25 g/L)

- Tuberculous peritonitis
- Peritoneal malignancy
- Budd–Chiari syndrome (hepatic vein occlusion or thrombosis)
- Pancreatic ascites
- Chylous ascites
- Meigs' syndrome

Clinical features

Ascites can usually only be recognised clinically when the amount of fluid present exceeds 1.5 L depending on body habitus: in the obese a greater quantity than this is necessary before there is clear evidence. The abdomen is distended evenly with fullness of the flanks, which are dull to percussion. Usually, shifting dullness is present but when there is a very large accumulation of fluid this sign is absent. In such cases, on flicking the abdominal wall, a characteristic fluid thrill is transmitted from one side to the other. In women, ascites must be differentiated from an enormous ovarian cyst.

Congestive heart failure, the most common cause of ascites, results in increased venous pressure in the vena cava and consequent obstruction to the venous outflow from the liver. The ascitic fluid is light yellow and of low specific gravity, about 1.010, with a low protein concentration (<25 g/L). Patients with constrictive pericarditis (Pick's disease) have both peritoneal and pleural effusions because of engorgement of the venae cavae consequent upon the diminished capacity of the right side of the heart. Ascites occurs with low plasma albumin concentrations, for example in patients with albuminuria or starvation. The ascites in this instance is caused by alterations in the osmotic pressure of the capillary blood and has a low specific gravity.

In cirrhosis, there is obstruction to the portal venous system, which is caused by obliterative fibrosis of the intrahepatic venous bed. In the Budd–Chiari syndrome (see Chapter 65), thrombosis or obstruction of the hepatic veins is responsible for obstruction to venous outflow from the liver. The ascites seen in patients with peritoneal metastases is caused by excessive exudation of fluid and lymphatic blockage. The fluid is dark yellow and frequently blood-stained. The specific gravity, 1.020 or over, and the protein content (>25 g/L) are high. Microscopic

examination often reveals cancer cells, especially if large quantities of fluid are 'spun down' to produce a concentrated deposit for sampling. Rarely, ascites and pleural effusion are associated with solid fibromas of the ovary (Meigs' syndrome). The effusions disappear when the tumour is excised.

Investigation

In addition to relevant investigations that may determine the underlying cause, e.g. liver and cardiac function tests, ultrasound and/or CT imaging (Figure 61.10) will determine much smaller quantities of ascites than possible clinically. These will often also diagnose aetiology, e.g. carcinomatosis, liver disease. Ascitic aspiration or tap (below) is now most commonly performed under imaging guidance to minimise the risk of visceral injury. The bladder having been emptied, puncture of the peritoneum is carried out under local anaesthetic using a moderately sized trocar and cannula. Alternatively, a peritoneal drain may be inserted. In cases where the effusion is caused by cardiac failure, the fluid must be evacuated slowly. Fluid is sent for microscopy/cytology, culture, including mycobacteria, and analysis of protein content and amylase. Unless other measures are taken the fluid soon reaccumulates, and repeated tapings remove valuable protein.

Treatment

Treatment of the specific cause is undertaken whenever possible; for example, if portal venous pressure is raised, it may be possible to lower it by treatment of the primary condition. Dietary sodium restriction to 200 mg/day may be helpful, but diuretics are usually required. In rare cases in which ascites accumulates rapidly after paracentesis and the patient is otherwise fit, permanent drainage of the ascitic fluid via a peritoneovenous shunt (e.g. LeVeen, Denver) may render the patient more comfortable. Similar in concept to shunts for hydrocephalus (see Chapter 43), a catheter (e.g. of silicone) is constructed with a valve so as to allow one-way flow from the peritoneum to a central vein (e.g. internal jugular). A chamber placed subcutaneously over the chest wall may be included for manual compression. Insertion is relatively simple. The complications include overloading the venous system, cardiac failure and disseminated intravascular coagulopathy. The frequency of these complications may be reduced by evacuating ascitic fluid and partially replacing it with normal saline at the time of shunt insertion.

Figure 61.10 Computed tomography scan showing gross ascites.

The procedure may also be used for patients with terminal malignant ascites, giving improved quality of life despite the risk of further dissemination of malignant cells.

Special cases

Chylous ascites

In some patients the ascitic fluid appears milky because of an excess of chylomicrons (triglycerides). Most cases are associated with malignancy, usually lymphomas; other causes are cirrhosis, tuberculosis, filariasis, nephrotic syndrome, abdominal trauma (including surgery), constrictive pericarditis, sarcoidosis and congenital lymphatic abnormality. The prognosis is poor unless the underlying condition can be cured. In addition to other measures used to treat ascites, patients should be placed on a fat-free diet with medium-chain triglyceride supplements.

TUMOURS OF THE PERITONEUM

Primary tumours

Primary tumours of the peritoneum are rare and in most cases take their origin not from the serous layer but from some adjacent structure, e.g. lipoma from appendices epiploicae, fibroma from connective tissue. Mesothelioma of the peritoneum is less frequent than in the pleural cavity but equally lethal. Asbestos is a recognised cause. It has a predilection for the pelvic peritoneum. Chemocytotoxic agents are the mainstay of treatment. Desmoid tumours which have a relationship to the peritoneum are considered under familial adenomatous polyposis (Chapter 69).

Secondary tumours

Carcinomatosis peritonei

This is a common terminal event in many cases of carcinoma of the stomach, colon, ovary or other abdominal organs and also of the breast and bronchus. The peritoneum, both parietal and visceral, is studded with secondary growths and the peritoneal cavity becomes filled with clear, straw-coloured or blood-stained ascitic fluid.

The main forms of peritoneal metastases are:

- discrete nodules – by far the most common variety;
- plaques varying in size and colour;
- diffuse adhesions – this form occurs at a late stage of the disease and gives rise, sometimes, to a 'frozen pelvis'.

Gravity probably determines the distribution of free malignant cells within the peritoneal cavity. Cells not caught in peritoneal folds gravitate into the pelvic pouches or into a hernial sac, the enlargement of which is occasionally the first indication of the condition. Implantation occurs also on the greater omentum, the appendices epiploicae and the inferior surface of the diaphragm. The main differential diagnosis is from tuberculous peritonitis (tubercles are greyish and translucent and closely resemble the discrete nodules of peritoneal carcinomatosis). Investigation and treatment are as for underlying malignancy.

Pseudomyxoma peritonei

This rare condition occurs more frequently in women. The abdomen is filled with a yellow jelly, large quantities of which are often encysted. The condition is associated with mucinous

Friedel Pick, 1867–1926, physician, Prague, The Czech Republic, described this disease in 1896.

Joe Vincent Meigs, 1892–1963, Professor of Gynaecology, Harvard University Medical School, Boston, MA, USA.

Harry LeVeen, Professor of Surgery, the University of South Carolina, SC, USA.

cystic tumours of the ovary and appendix. Recent studies suggest that most cases arise from a primary appendiceal tumour with secondary implantation on to one or both ovaries. It is often painless and there is frequently no impairment of general health. Pseudomyxoma peritonei does not give rise to extraperitoneal metastases. Although an abdomen distended with what seems to be fluid that cannot be made to shift should raise the possibility, the diagnosis is more often suggested by ultrasound and CT scanning or made at operation. At laparotomy, masses of jelly are scooped out. The appendix, if present, should be excised together with any ovarian tumour. Unfortunately, recurrence is inevitable, but patients may gain symptomatic benefit from repeated 'debulking' surgery. Occasionally, the condition responds to radioactive isotopes or intraperitoneal chemotherapy. The role of early radical peritoneal excision is uncertain.

Peritoneal loose bodies (peritoneal mice)

Peritoneal loose bodies (peritoneal mice) may be confused with a small tumour but almost never cause symptoms. One or more may be found in a hernial sac or in the pouch of Douglas. The loose body may come from an appendix epiploica that has undergone axial rotation followed by necrosis of its pedicle and detachment but they are also found in those who suffer from subacute attacks of pancreatitis. These hyaline bodies attain the size of a pea or bean and contain saponified fat surrounded by fibrin.

ADHESIONS

Pathophysiology

Adhesions are strands of fibrous tissue that form, usually as a result of surgery, between surgically injured tissues. After injury, there is bleeding and an increase in vascular permeability with extravasation of fibrinogen-rich fluid from the injured surfaces forming a temporary fibrin matrix. An inflammatory response ensues with cell migration, release of cytokines, and activation of the coagulation cascade. The activation of the coagulation system results in thrombin formation, which is necessary for the conversion of fibrinogen to fibrin. In the absence of fibrinolysis, adhesions will form within 5–7 days as the matrix gradually becomes more organised with collagen secretion by fibroblasts. Fibrinolysis is therefore the key factor in determining whether an adhesion persists. This is governed by several cascades and activators that may account for interindividual differences (Chapter 59). Of great importance however to the surgeon is the fact that ischaemic tissue loses its ability to break down fibrin and inhibits fibrinolysis in adjacent tissues.

Complications

The most common adhesion-related problem is small bowel obstruction (SBO). Adhesions are the most frequent cause of SBO in the developed world and are responsible for 60–70 per cent of SBO (see Chapter 69). Adhesions are implicated as a major cause of secondary infertility (beyond the remit of this text). The relationship of adhesions to chronic abdominal and pelvic pain is contentious. Unguided division of adhesions has not been shown to reduce chronic abdominal pain in definitive randomised controlled trials although conscious pain mapping (laparoscopy under local anaesthesia) to direct lysis may improve success rates.

Prevention

Because of the scale of the problem there has been significant research into ways of preventing postoperative adhesion formation. Minimising the production of ischaemic tissue by careful operative technique, including meticulous control of bleeding, remain however the most critical concepts. The evolution of laparoscopic bowel surgery has been shown by collective review data to result in reduced adhesion-related readmissions for a number of abdominal and pelvic procedures, e.g. cholecystectomy, hysterectomy and colectomy. It should be noted however that only one randomised controlled trial (after Crohn's resection) has ever shown a definitive effect and this was not confirmed by evidence synthesis at Cochrane review.

The effect of a number of drugs including anti-inflammatory drugs like aspirin and steroids, some hormones, anticlotting agents, antibiotics, vitamin E and even methylene blue have been investigated in adhesion prevention but have not achieved widespread use either because of side effects or lack of consistent evidence of effectiveness. Many barrier methods of reducing adhesions have also been trialled. Adept® (4 per cent icodextrin solution) is a solution applied inside the abdomen at the time of surgery and has been shown to reduce the extent and severity of adhesion formation in animal models. It has also been used widely as a peritoneal dialysis solution for many years. Interceed TC7® is a mesh-like product (oxidised regenerated cellulose) which quickly forms a soft gelatinous mass around healing tissues and is absorbed within 2 weeks. It has been shown to significantly reduce the number of adhesions at the site where it is used. However, it is worth noting that a reduction in the number of adhesions in such studies does not necessarily equate to a reduction in adhesion-related problems in the future. In a review of seven randomised trials looking at a similar barrier-type product (hyaluronic acid/carboxymethyl membrane), there was a significant reduction in the incidence, extent and severity of adhesions but no reduction in the incidence of intestinal obstruction or operative intervention. Such barriers when placed around bowel anastomosis also led to a significant increase in the anastomotic leaks. For these reasons barrier approaches have not gained popularity.

Special forms of intraperitoneal fibrosis

Sclerosing encapsulating peritonitis

Also known as abdominal cocoon syndrome, sclerosing encapsulating peritonitis (SEP) is described in patients as a complication of long-term peritoneal dialysis or portovenous shunting. The peritoneal cavity becomes obliterated as a result of gross subserosal thickening by fibrosis leading to bowel obstruction and other sequelae. Surgery should be undertaken with trepidation and avoided if possible.

Diffuse fibromatosis

This is a variant of intra-abdominal fibromatosis (IAF) and is actually a rare tumour characterised by an abnormal proliferation of myofibroblasts. Although non-metastasising, and said to be benign, it can nevertheless prove widely invasive, compressing and infiltrating surrounding tissues such as the bowel and mesentery with complications thereof. IAF is very rare within the general population but has a recognised association with familial adenomatous polyposis (FAP).

THE OMENTUM

Rutherford Morison called the greater omentum 'the abdominal policeman'. The greater omentum attempts, often successfully, to limit intraperitoneal infective and other noxious processes (Figure 61.11). For instance, an acutely inflamed appendix is often found wrapped in omentum, and this saves many patients from developing diffuse peritonitis. Some sufferers of herniae are also greatly indebted to this structure, for it often plugs the neck of a hernial sac and prevents a coil of intestine from entering and becoming strangulated. It can, of course, also be a cause of obstruction (acting as a large adhesion). The omentum is usually involved in tuberculous peritonitis and carcinomatosis of the peritoneum.

Torsion of the omentum

Torsion of the omentum is a rare emergency and consequently is seldom diagnosed correctly. It is usually mistaken for appendicitis with somewhat abnormal signs. It may be primary, or secondary to adhesion of the omentum to an old focus of infection or hernia. The patient is most frequently a middle-aged, obese man. A tender lump may be present in the abdomen. The blood supply having been jeopardised, the twisted mass sometimes becomes gangrenous, in which case bacterial peritonitis may follow. Treatment is surgical; the pedicle above the twist is ligated securely and the mass removed.

Figure 61.11 The greater omentum. (a) Normal; (b) in appendicitis; (c) in a (comparatively small) laceration of the spleen.

THE MESENTERY

Mesenteric injury

A wound of the mesentery can follow severe abdominal contusion and is a cause of haemoperitoneum. More commonly, it is injured by a torsional force, so-called seatbelt syndrome. This occurs during a vehicular collision when a seatbelt is being worn with sudden deceleration resulting in a torn mesentery. This possibility should be borne in mind, particularly as multiple injuries may distract attention from this injury (the management of abdominal trauma is covered in Chapter 23). Aside from control of any ongoing haemorrhage, associated ischaemic or ruptured gut will require resection.

Ischaemia

Torsion of the mesentery is covered under midgut volvulus and volvulus of the small intestine (see Chapter 70). Embolism and thrombosis of mesenteric vessels leading to intestinal ischaemia are also covered in Chapter 70.

Inflammation

A number of somewhat miscellaneous conditions are best described under this umbrella term.

Acute non-specific ileocaecal mesenteric adenitis

Non-specific mesenteric adenitis was so named to distinguish it from specific (tuberculous) mesenteric adenitis. It is now much more common than the tuberculous variety. The aetiology often remains unknown, although some cases are associated with *Yersinia* infection of the ileum. In other cases, an unidentified virus is blamed. In about 25 per cent of cases, a respiratory infection precedes an attack of non-specific mesenteric adenitis.

This self-limiting disease is never fatal but may be recurrent. Its significance thus mainly lies in its differential diagnosis with appendicitis in children.

Diagnosis

During childhood, acute non-specific mesenteric adenitis is a common condition. The typical history is one of short attacks of central abdominal pain lasting from 10 to 30 minutes, commonly associated with vomiting. The patient seldom looks ill. In more than half of the cases the temperature is elevated. Abdominal tenderness is poorly localised, and when present, shifting tenderness is a valuable sign for differentiating the condition from appendicitis. The neck, axillae and groins should be palpated for enlarged lymph nodes. There is often a leukocytosis of 10 000–12 000 μ L ($10\text{--}12 \times 10^9$ L) or more on the first day of the attack, but this falls on the second day.

Treatment

When the diagnosis can be made with assurance, bed rest and simple analgesia is the only treatment necessary. If at a second examination a few hours later, acute appendicitis cannot be excluded, it is safer to perform either appendicectomy or diagnostic laparoscopy. If surgery is mistakenly undertaken, there is a small increase in the amount of peritoneal fluid. The ileocaecal mesenteric lymph nodes are enlarged and can be seen and felt between the leaves of the mesentery. In very acute cases they are distinctly red, and many of them are the size of a walnut. The nodes nearest the attachment of the mesentery are the largest. They are not adherent to their peritoneal coats and, if a small incision is made through the overlying peritoneum, a node is extruded easily.

Tuberculosis of the mesenteric lymph nodes

Tuberculous mesenteric lymphadenitis is considerably less common than acute non-specific lymphadenitis. Tubercle bacilli, usually, but not necessarily, bovine, are ingested and enter the mesenteric lymph nodes by way of Peyer's patches. Sometimes only one lymph node is infected; usually there are several; occasionally massive involvement occurs. The presentation may be with abdominal pain (a rare differential for appendicitis) or with general constitutional symptoms (pyrexia, weight loss, etc.). Calcified lymph nodes may be demonstrated on a plain radiograph of the abdomen where they must be distinguished from other calcified lesions, e.g. renal or ureteric stones.

Misty mesentery

The term 'misty mesentery' indicates a pathological increase in mesenteric fat attenuation at CT (Figure 61.12). It is frequently observed on multidetector CT (MDCT) scans performed during daily clinical practice and may be caused by various pathological conditions, including oedema, inflammation (especially in association with pancreatitis), haemorrhage, neoplastic infiltration (especially otherwise occult lymphoma) or sclerosing mesenteritis. In patients suffering from acute abdominal disease, misty mesentery may be considered a feature of the underlying disease. Otherwise, it may represent an incidental finding on MDCT performed for other reasons. Follow-up scans may be required to dictate whether further investigation is required depending on progression or resolution. It should be noted that the term 'mesenteric panniculitis' is frequently used synonymously with 'misty mesentery'. Correctly this term should be reserved for the mesenteric manifestation of Weber-Christian disease; isolated lipodystrophy and mesenteric lipogranuloma. It is a very rare (2–300 cases reported worldwide) benign inflammatory or fibrotic change in the mesentery of the bowel.

Figure 61.12 Computed tomography scan showing 'misty mesentery' in a patient with probable peritoneal inflammation secondary to acute pancreatitis (courtesy of Dr K Patel, Homerton University Foundation Trust, London, UK).

Mesenteric cysts

Cysts may occur in the mesentery of either the small intestine (60 per cent) or the colon (40 per cent) and can be classified as:

- chylolymphatic;
- enterogenous;
- urogenital remnant (actually retroperitoneal but project into peritoneum);
- dermoid.

Pathology

Chylolymphatic cyst

This is the most common variety, probably arising in congenitally misplaced lymphatic tissue that has no efferent communication with the lymphatic system (most frequently in the mesentery of the ileum). The thin wall of the cyst, which is composed of connective tissue lined by flat endothelium, is filled with clear lymph or, less frequently, with chyle varying in consistency from watered milk to cream. Occasionally, the cyst attains a great size. More often unilocular than multilocular, a chylolymphatic cyst is almost invariably solitary, although there is an extremely rare variety in which myriads of cysts are found in the various mesenteries of the abdomen. A chylolymphatic cyst has a blood supply that is independent from that of the adjacent intestine and, thus, enucleation is possible without the need for resection of gut.

Enterogenous cysts

These are believed to be derived either from a diverticulum of the mesenteric border of the intestine that has become sequestered from the intestinal canal during embryonic life or from a duplication of the intestine (see Chapter 8). An enterogenous cyst has a thicker wall than a chylolymphatic cyst and it is lined by mucous membrane, sometimes ciliated. The content is mucinous and is either colourless or yellowish brown as a result of past haemorrhage. The muscle in the wall of an enteric duplication cyst and the bowel with which it is in contact have a common blood supply; consequently, removal of the cyst always entails resection of the related portion of intestine.

Urogenital remnant

A cyst developing in the retroperitoneal space (see below) often attains very large dimensions and has first to be distinguished from a large hydronephrosis. Even after the latter condition has been eliminated by scanning or urography, a retroperitoneal cyst can seldom be distinguished with certainty from a retroperitoneal tumour until displayed at operation. The cyst may be unilocular or multilocular. Many of these cysts are believed to be derived from a remnant of the Wolffian duct, in which case they are filled with clear fluid.

Clinical features

These are shown for mesenteric cysts in general in Summary box 61.13.

Investigation and treatment

Ultrasound and CT scanning will demonstrate the lesion and may allow diagnosis of cyst type (Figure 61.14a,b). There are no suitable medical therapies. The goal of surgical therapy is complete excision of the mass. The preferred treatment of

Summary box 61.13**Mesenteric cysts: clinical features**

- Cysts occur most commonly in adults with a mean age of 45 years
- Twice as common in women as in men
- Rare – incidence around 1 per 140 000
- Approximately one-third of cases occur in children younger than 15 years
- The mean age of children affected is 4.9 years
- The most common presentation is of a painless abdominal swelling with characteristic physical signs
 - there is a fluctuant swelling near the umbilicus
 - the swelling moves freely in a plane at right angles to the attachment of the mesentery (Tillaux's sign) (Figure 61.13)
 - there is a zone of resonance around the cyst
- Other presentations are with recurrent attacks of abdominal pain with or without vomiting (pain resulting from recurring temporary impaction of a food bolus in a segment of bowel narrowed by the cyst or possibly from torsion of the mesentery) and acute abdominal catastrophe, due to
 - torsion of that portion of the mesentery containing the cyst
 - rupture of the cyst, often as a result of a comparatively trivial accident
 - haemorrhage into the cyst
 - infection

mesenteric cysts is enucleation, although bowel resection is frequently required to ensure that the remaining bowel is viable. Bowel resection may be required in 50–60 per cent of children with mesenteric cysts, whereas resection is necessary in about one-third of adults (Figure 61.14c). If enucleation or resection is not possible because of the size of the cyst or because of its location deep within the root of the mesentery, the third option is partial excision with marsupialisation of the remaining cyst into the abdominal cavity. Approximately 10 per cent of patients require this form of therapy; If marsupialisation is performed, the cyst lining should be sclerosed with 10 per cent glucose solution, diathermy, or tincture of iodine to minimise recurrence. Recurrence rates vary from 0 to 13 per cent.

Differential diagnosis

The following, although not being mesenteric cysts in the true meaning of the term, give rise to the same physical signs:

- serosanguinous cyst, probably traumatic in origin although a history of an accident is seldom obtained;
- tuberculous abscess of the mesentery;
- hydatid cyst of the mesentery.

Neoplasms of the mesentery

The mesentery is necessarily affected by local lymphatic spread of carcinoma arising from the peritoneal viscera. Other benign and malignant tumours are less common (Summary box 61.14).

Tumours situated in the mesentery give rise to physical signs that are similar to those of a mesenteric cyst, the sole exception being that they sometimes feel solid. If indicated, a benign tumour of the mesentery is excised in the same way as an

enterogenous mesenteric cyst, i.e. with resection of the adjacent intestine. A malignant tumour of the mesentery requires biopsy confirmation and specific, usually non-surgical, treatment, e.g. chemotherapy for lymphoma.

Summary box 61.14**Mesenteric tumours****Benign**

- Lipoma
- Fibroma
- Fibromyxoma

Malignant

- Lymphoma
- Secondary carcinoma

THE RETROPERITONEAL SPACE**Retroperitoneal chronic inflammation/fibrosis**

This is a relatively rare diagnosis characterised by the development of a flat grey/white plaque of tissue which is found first in the low lumbar region but then spreads laterally and upwards to encase the common iliac vessels, ureters and aorta. Histological appearances vary from active inflammation with a high cellular content interspersed with bundles of collagen through to one of acellularity and mature fibrosis/calcification. Its aetiology is obscure in most cases (idiopathic) being allied to other fibromatoses (others being Dupuytren's contracture and Peyronie's disease). In other patients the cause is known (Summary box 61.15).

Figure 61.13 A mesenteric cyst moves freely in the direction of the arrows, i.e. at right angles to the attachment of the mesentery (Tillaux's sign).

Figure 61.14 A mesenteric enterogenous cyst in a 37-year-old female presenting with an asymptomatic palpable abdominal mass: (a) ultrasound findings; (b) computed tomography findings; (c) intraoperative findings requiring en masse small bowel resection (courtesy of Mr F Olagbaiye, Homerton University Foundation Trust, London, UK).

Summary box 61.15

Causes of retroperitoneal fibrosis

Benign

- Idiopathic (Ormond's disease)
- Chronic inflammation
- Extravasation of urine
- Retroperitoneal irritation by leakage of blood or intestinal content
- Aortic aneurysm (inflammatory type)
- Trauma
- Drugs (chemotherapeutic agents and previously methysergide)

Malignant

- Lymphoma
- Carcinoid tumours
- Secondary deposits (especially from carcinoma of stomach, colon, breast and prostate)

The clinical presentation may be one of ill-defined chronic backache or may occur as a result of compromise to involved structures, e.g. lower limb or scrotal oedema secondary to venous occlusion, or chronic renal failure secondary to ureteric obstruction. Treatment will be directed to the cause, to the modification of disease activity when appropriate, e.g. immune suppression with steroids and restoration of flow in affected structures, e.g. ureteric stenting.

Retroperitoneal (psoas) abscess

The retroperitoneal space can also be a site for abscess formation which for practical purposes is almost synonymous with psoas abscess. Psoas abscess is a relatively uncommon diagnosis whose true incidence is not well described. At the beginning of the twentieth century, psoas abscess was mainly caused by tuberculosis of the spine (Pott's disease). With the decline of *Mycobacterium tuberculosis* as a major pathogen in developed countries a psoas abscess was mostly found secondary to direct spread of infection from the inflamed \pm perforated digestive or urinary tract. In recent years, a primary psoas abscess due to haematogenous spread from an occult source is more common, especially in immunocompromised and older patients as well as in association with intravenous drug misuse.

Clinical presentation is with back pain, lassitude and fever. A swelling may point to the groin as it tracks along ileopsoas (see Chapter 73). Pain may be elicited by passive extension of the hip or a fixed flexion of the hip evident on inspection.

Radiological investigation is via CT scanning (Figure 61.15) and treatment usually by percutaneous CT-guided drainage and appropriate antibiotic therapy.

Retroperitoneal tumours

Although swellings in the retroperitoneum may include abscess, haematoma, cysts (see above) and spread of malignancy from retroperitoneal organs (kidney, ureter, adrenal), the term retroperitoneal tumour is usually confined to primary tumours arising in other tissues in this region, e.g. muscles, fat, lymph nodes and nerves. The management of such tumours is now frequently by referral to a specialist centre and this should be done before biopsy which may compromise subsequent surgical cure. The two most common are briefly described.

Retroperitoneal lipoma

The patient may seek advice on account of a swelling or because of indefinite abdominal pain. Women are more often affected. These swellings sometimes reach an immense size. Diagnosis is usually by ultrasound and CT scanning. A retroperitoneal lipoma sometimes undergoes myxomatous degeneration, a complication that does not occur in a lipoma in any other part of the body. Moreover, a retroperitoneal lipoma is often malignant (liposarcoma) (see below) and may increase rapidly in size.

Retroperitoneal sarcoma

Retroperitoneal sarcomas are rare tumours accounting for only 1–2 per cent of all solid malignancies (10–20 per cent of all sarcomas are retroperitoneal). The peak incidence is in the fifth decade of life, although they can occur at almost any age. The most common types of retroperitoneal soft tissue sarcomas in adults vary from study to study. However, in most studies, the most frequently encountered cell types are:

Baron Guillaume Dupuytren, 1777–1835, Surgeon in Chief, Hôtel Dieu, Paris, France, described this condition in 1831.

Francois de la Peyronie, 1678–1747, surgeon to King Louis XIV of France and founder of the Royal Academy of Surgery, Paris, France.

JK Ormond, an American urologist.

Figure 61.15 Representative sagittal computed tomography reconstruction of a right-sided psoas abscess (courtesy of Dr K Patel, Homerton University Foundation Trust, London, UK).

- liposarcoma;
- leiomyosarcoma;
- malignant fibrous histiocytoma (MFH).

Clinical features

Patients with sarcomas present late, because these tumours arise in the large potential spaces of the retroperitoneum and can grow very large without producing symptoms. Moreover, when symptoms do occur, they are non-specific, such as abdominal pain and fullness, and are easily dismissed as being caused by other less serious processes. Retroperitoneal sarcomas, therefore, are usually very large at the time of presentation.

Investigation

Detailed multiplanar imaging (CT + magnetic resonance imaging) with reconstructions are required not only for tumour

detection, staging and operative planning, but also for guiding percutaneous or surgical biopsy of these tumours. Such biopsies have a greater role than for other sarcomas.

Treatment

The definitive treatment of primary retroperitoneal sarcomas is surgical resection. Chemotherapy and radiotherapy without surgical debulking have rarely been beneficial, when used alone or in combination. A multidisciplinary team approach with imaging review will be required when assessing operability (based on adjacency or involvement of vital structures) and approach. Up to 75 per cent of retroperitoneal sarcoma resections involve resection of at least one adjoining intra-abdominal visceral organ (commonly large or small bowel or kidney). The most common types of vascular involvement precluding resection are involvement of the proximal superior mesenteric vessels or involvement of bilateral renal vessels.

Prognosis

In the vast majority of sarcomas, cell type has no impact on treatment and long-term survival. Survival rates are, in general, poor, even after complete resection, these being in the order of 35–50 per cent (excluding low grade liposarcomas, which may frequently be cured by resection).

LEARNING OBJECTIVES

To understand:

- The anatomy and physiology of the oesophagus and their relationship to disease
- The clinical features, investigations and treatment of benign and malignant disease with particular reference to the common adult disorders

BACKGROUND

Surgical anatomy

The oesophagus is a muscular tube, approximately 25 cm long, mainly occupying the posterior mediastinum and extending from the upper oesophageal sphincter (the cricopharyngeus muscle) in the neck to the junction with the cardia of the stomach. The musculature of the upper oesophagus, including the upper sphincter, is striated. This is followed by a transitional zone of both striated and smooth muscle with the proportion of the latter progressively increasing so that, in the lower half of the oesophagus, there is only smooth muscle. It is lined throughout with squamous epithelium. The parasympathetic nerve supply is mediated by branches of the vagus nerve that has synaptic connections to the myenteric (Auerbach's) plexus. Meissner's submucosal plexus is sparse in the oesophagus.

The upper sphincter consists of powerful striated muscle. The lower sphincter is more subtle, and is created by the asymmetrical arrangement of muscle fibres in the distal oesophageal wall just above the oesophagogastric junction. It is helpful to remember the distances 15, 25 and 40 cm for anatomical location during endoscopy (Figure 62.1).

Physiology

The main function of the oesophagus is to transfer food from the mouth to the stomach in a coordinated fashion. The initial movement from the mouth is voluntary. The pharyngeal phase of swallowing involves sequential contraction of the oropharyngeal musculature, closure of the nasal and respiratory passages, cessation of breathing and opening of the upper oesophageal sphincter. Beyond this level, swallowing is involuntary. The body of the oesophagus propels the bolus through a relaxed lower oesophageal sphincter (LOS) into the stomach, taking air with it (Figure 62.2). This coordinated oesophageal wave that follows a conscious swallow is called primary peristalsis. It is under vagal control, although there are specific neurotransmitters that control the LOS.

The upper oesophageal sphincter is normally closed at rest and serves as a protective mechanism against regurgitation of

oesophageal contents into the respiratory passages. It also serves to stop air entering the oesophagus other than the small amount that enters during swallowing.

The LOS is a zone of relatively high pressure that prevents gastric contents from refluxing into the lower oesophagus (Figure 62.3). In addition to opening in response to a primary peristaltic wave, the sphincter also relaxes to allow air to escape from the stomach and at the time of vomiting. A variety of factors influence sphincter tone, notably food, gastric distension, gastrointestinal hormones, drugs and smoking. The arrangement of muscle fibres, their differential responses to specific neurotransmitters and the relationship to diaphragmatic contraction all contribute to the action of the LOS. The presence of the physiological sphincter was first demonstrated by Code using manometry with small balloons. Nowadays, LOS pressure is measured by perfused tubes or microtransducers. The normal LOS is 3–4 cm long

Figure 62.1 Endoscopic landmarks. Distances are given from the incisor teeth. They vary slightly with the build of the individual.

Figure 62.2 A bolus of barium or food usually takes air with it into the stomach.

and has a pressure of 10–25 mmHg. Accurate measurement of sphincter relaxation is achieved using a device (Dent sleeve) that straddles the high-pressure zone.

Manometry is also used to assess the speed and amplitude of oesophageal body contractions and ensure that peristalsis is propagated down the entire length of the oesophagus (Figure 62.4). Secondary peristalsis is the normal reflex response to a stubborn food bolus or refluxed material designed to clear the oesophagus by a contraction that is not preceded by a conscious swallow. It is worth remembering that the majority of clearance swallows to neutralise refluxed gastric acid are, however, achieved by primary peristalsis, which carries saliva with its high bicarbonate content down to the lower oesophagus. Tertiary contractions are non-peristaltic waves that are infrequent (<10 per cent) during laboratory-based manometry, although readily detected if manometry is undertaken while the patient eats a meal (Figure 62.5).

Symptoms

Dysphagia

Dysphagia is used to describe difficulty with swallowing. When there is a problem with swallowing in the voluntary (oral or pharyngeal) phases, patients will usually say that they cannot swallow properly, but they do not characteristically describe 'food sticking'. Instead, when they try to initiate a conscious swallow, food fails to enter the oesophagus, stays in the mouth or enters the airway causing coughing or spluttering. Virtually all causes of this type of dysphagia are chronic neurological or muscular diseases. Oesophageal dysphagia occurs in the involuntary phase and is characterised by a sensation of food sticking. The nature of this type of dysphagia is often informative regarding a likely diagnosis. Dysphagia may occur acutely or in a chronic fashion, can affect solids and/or fluids and be intermittent or progressive. While many patients point to a site of impaction, this is unreliable.

Figure 62.3 Correlation between the radiological appearances of a barium column and the lower oesophageal sphincter open and closed. The three curves on the right, set up vertically, show the pH gradient, the mucosal potential difference (PD) marking the junction of squamous and columnar epithelium and the high-pressure zone of the sphincter.

Figure 62.4 Manometric recording from the body of a normal oesophagus. Peristalsis is seen in the first and last panels, but other waves are simultaneous. Non-peristaltic simultaneous contractions are called 'tertiary contractions'.

Odynophagia

Odynophagia refers to pain on swallowing. Patients with reflux oesophagitis often feel retrosternal discomfort within a few seconds of swallowing hot beverages, citrus drinks or alcohol. Odynophagia is also a feature of infective oesophagitis and may be particularly severe in chemical injury.

Regurgitation and reflux

Regurgitation and reflux are often used synonymously. It is helpful to differentiate between them, although it is not always possible. Regurgitation should strictly refer to the return of oesophageal contents from above a functional or mechanical obstruction. Reflux is the passive return of gastroduodenal contents to the mouth as part of the symptomatology of gastro-oesophageal reflux disease (GORD). Loss of weight, anaemia, cachexia, change of voice due to refluxed material irritating the vocal cords and cough or dyspnoea due to tracheal aspiration may all accompany regurgitation and/or reflux.

Chest pain

Chest pain similar in character to angina pectoris may arise from an oesophageal cause, especially gastro-oesophageal reflux and motility disorders. Exercise-induced chest pain can be due to reflux (Summary box 62.1).

Summary box 62.1

Symptoms of oesophageal disease

- Difficulty in swallowing described as food or fluid sticking (oesophageal dysphagia) must rule out malignancy
- Pain on swallowing (odynophagia) suggests inflammation and ulceration
- Regurgitation or reflux (heartburn) common in gastro-oesophageal reflux disease
- Chest pain is difficult to distinguish from cardiac pain

Investigations

Radiography

Contrast radiography has been somewhat overshadowed by endoscopy but remains a useful investigation for demonstrating narrowing, space-occupying lesions, anatomical distortion or abnormal motility. An adequate barium swallow should be tailored to the problem under investigation. It may be helpful to give a solid bolus (bread or marshmallow) if a motility disorder is suspected. Video recording is useful to allow subsequent replay and detailed analysis. Barium radiology is, however, inaccurate in the diagnosis of gastro-oesophageal reflux, unless reflux is gross, and should not be used for this purpose. Plain radiographs will show some foreign bodies.

Cross-sectional imaging by computed tomography (CT) scanning is now an essential investigation in the assessment of neoplasms of the oesophagus and can be used in place of a contrast swallow to demonstrate perforation. The role of CT and other cancer-specific tests is described later.

Figure 62.5 Triple water-perfused tube study of normal lower oesophagus and lower oesophageal sphincter. Note that the swallowing contractions (S) in the body of the oesophagus are sequential, i.e. peristaltic.

Endoscopy

Endoscopy is necessary for the investigation of most oesophageal conditions. It is required to view the inside of the oesophagus and the oesophagogastric junction, to obtain a biopsy or cytology specimen, for the removal of foreign bodies and to dilate strictures. Traditionally, there are two types of instrument available, the rigid oesophagoscope and the flexible video endoscope, but the rigid instrument is now virtually obsolete.

For flexible video gastroduodenoscopy, general anaesthesia is not required; most examinations can be done on an outpatient basis, and the quality of the magnified image is superb. The technology associated with video endoscopy continues to improve. Novel techniques that rely on fluorescence and narrow band imaging to enhance visual contrast are becoming increasingly used for the identification of mucosal abnormalities that are not easily seen with white light, for instance in patients with Barrett's oesophagus undergoing endoscopic surveillance.

As a matter of routine, the stomach and duodenum are examined as well as the oesophagus. If a stricture is encountered, it may be helpful to dilate it to allow a complete inspection of the upper gastrointestinal tract, but this decision should be dictated by clinical circumstances and an appreciation of the perforation risk.

Endosonography

Endoscopic ultrasonography relies on a high-frequency (5–30 MHz) transducer located at the tip of the endoscope to provide highly detailed images of the layers of the oesophageal wall and mediastinal structures close to the oesophagus. Radial echoendoscopes have a rotating transducer that creates a circular image with the endoscope in the centre, and this type of scanner is widely used to create diagnostic transverse sectional images at right angles to the long axis of the oesophagus (Figure 62.6). Linear echoendoscopes produce a sectoral image in the line of the endoscope and are used to biopsy submucosal oesophageal lesions or mediastinal masses such as lymph nodes (Figure 62.7). Radial scanners without optical components are available for passage through narrow strictures over a guidewire, and there are even catheter probes that can be passed down the endoscope biopsy channel.

Oesophageal manometry

Manometry is now widely used to diagnose oesophageal motility disorders. Recordings are usually made by passing a multilumen catheter with three to eight recording orifices at different levels down the oesophagus and into the stomach. Electronic microtransducers that are not influenced by changes in patient position during the test have gradually supplanted perfusion systems. With either system, the catheter is withdrawn progressively up the oesophagus, and recordings are taken at intervals of 0.5–1.0 cm to measure the length and pressure of the LOS and assess motility in the body of the oesophagus during swallowing. High-resolution manometry uses a multiple (up to 30) microtransducer catheter with the results displayed as spatiotemporal plots; this system is likely to supplant conventional manometry.

Twenty-four hour pH and combined pH-impedance recording

Prolonged measurement of pH is now accepted as the most accurate method for the diagnosis of gastro-oesophageal reflux. It is particularly useful in patients with atypical reflux symp-

Figure 62.6 Radial endosonography indicating wall layers as alternating hyper- and hypoechoic bands.

toms, those without endoscopic oesophagitis and when patients respond poorly to intensive medical therapy. A small pH probe is passed into the distal oesophagus and positioned 5 cm above the upper margin of the LOS, as defined by manometry. The probe is connected to a miniature digital recorder that is worn on a belt and allows most normal activities. Patients mark symptomatic events such as heartburn. A 24-hour recording period is usual, and the pH record is analysed by an automated computer program. An oesophageal pH < 4 at the level of the pH electrode is conventionally considered the cut-off value and, in most oesophageal laboratories, the total time when pH is < 4 in a 24-hour period does not exceed 4 per cent in a healthy adult. Patterns of reflux and the correlation between symptoms and oesophageal pH < 4 can be calculated. Most laboratories use a scoring system (Johnson–DeMeester) to create a numerical value, above which reflux is considered pathological.

Figure 62.7 Linear endosonography with the needle traversing an ultrasound plane for guided biopsy.

Radiotelemetry pH probes are also available that can be fixed to the oesophageal wall endoscopically without the need for a transnasal catheter. In the last few years, the introduction of catheter assemblies that incorporate multiple electrodes along the length of the catheter as well as a pH probe has resulted in combined measurement of pH and electrical impedance. Impedance measurement differentiates antegrade from retrograde bolus transit, gas from liquid and provides a reliable measure of non-acid or weakly acidic events that cause symptoms. This may be important in the identification of patients with non-erosive reflux disease on endoscopy.

Therapeutic procedures

Dilatation of strictures

Stricture dilatation is essentially undertaken for benign conditions and should be used with caution in the context of malignant disease. The risks associated with dilatation for malignant disease are discussed later. The advent of guidewire-directed dilatation of the oesophagus in the 1970s was a major advance over earlier blind dilatation systems. Their use is now considered standard practice. There are many different designs, but essentially they are solid dilators of increasing diameter. To restore normal swallowing, a stricture should be dilated to at least 16 mm in diameter. A guidewire is passed down the biopsy channel of an endoscope and through the stricture under vision. If the stricture is long or tortuous, this should be undertaken under radiological guidance to ensure that the guidewire passes easily into the stomach. The endoscope is withdrawn, leaving the guidewire in place, and graduated dilators are passed over the guidewire, sometimes with radiographic screening for safety purposes. The dilatation of reflux-induced strictures is usually straightforward. These strictures are nearly always short and at the oesophagogastric junction, so that the stomach is visible through the narrowed segment. Radiological control is rarely needed. Conversely, distal oesophageal adenocarcinomas extending into the stomach are often soft, friable and tortuous to negotiate.

Balloons with inflation diameters of 25–40 mm may also be used for dilatation. Pneumatic dilatation is widely used to disrupt the non-relaxing LOS in achalasia.

Thermal recanalisation

Various types of laser (mainly Nd-YAG), bipolar diathermy, injection of absolute alcohol or argon-beam plasma coagulation have all been used successfully to ablate tissue in order to recanalise the oesophagus.

CONGENITAL ABNORMALITIES

See Chapter 8.

FOREIGN BODIES IN THE OESOPHAGUS

All manner of foreign bodies have become arrested in the oesophagus (Figure 62.8). Button batteries may be a troublesome problem in children. The most common impacted material is food, and this usually occurs above a significant pathological lesion (Figure 62.9). Plain radiographs are often useful for foreign bodies, but modern denture materials are not always radiopaque. A contrast examination is not usually required and only makes endoscopy more difficult (Summary box 62.2).

Summary box 62.2

Foreign bodies

- The most common is a food bolus, which usually signifies underlying disease
- It is usually possible to remove foreign bodies by flexible endoscopy
- Beware of button batteries in the oesophagus

Foreign bodies that have become stuck in the oesophagus should be removed by flexible endoscopy using suitable grasping forceps, a snare or a basket. If the object may injure the oesophagus on withdrawal, an overtube can be used, and the endoscope and object can be withdrawn into the overtube before removal. Button batteries can be a particular worry as they are difficult to grasp, and it is tempting to push them on into the stomach. However, an exhausted battery may rapidly corrode in the

Figure 62.8 False teeth impacted in the oesophagus. (Note: modern dentures are usually radiolucent.)

Figure 62.9 An impacted meat bolus at the lower end of the oesophagus. This may be the first presentation of a benign stricture or a malignant tumour.

gastrointestinal tract and is best extracted. A multiwire basket of the type used for gallstone retrieval nearly always works. An impacted food bolus will often break up and pass on if the patient is given fizzy drinks and confined to fluids for a short time. The cause of the impaction must then be investigated. If symptoms are severe or the bolus does not pass, it can be extracted or broken up at endoscopy.

PERFORATION

Perforation of the oesophagus is usually iatrogenic (at therapeutic endoscopy) or due to 'barotrauma' (spontaneous perforation). Many instrumental perforations can be managed conservatively, but spontaneous perforation is often a life-threatening condition that regularly requires surgical intervention (Summary box 62.3).

Summary box 62.3

Perforation of the oesophagus

- Potentially lethal complication due to mediastinitis and septic shock
- Numerous causes, but may be iatrogenic
- Surgical emphysema is virtually pathognomonic
- Treatment is urgent; it may be conservative or surgical, but requires specialised care

Barotrauma (spontaneous perforation, Boerhaave syndrome)

This occurs classically when a person vomits against a closed glottis. The pressure in the oesophagus increases rapidly, and the oesophagus bursts at its weakest point in the lower third, sending a stream of material into the mediastinum and often the pleural cavity as well. The condition was first reported by Boerhaave, who reported the case of a grand admiral of the Dutch fleet who was a glutton and practised autoemesis. Boerhaave syndrome is the most serious type of perforation because of the large volume of material that is released under pressure. This causes rapid chemical irritation in the mediastinum and pleura followed by infection if untreated. Barotrauma has also been described in relation to other pressure events when the patient strains against a closed glottis (e.g. defaecation, labour, weight-lifting).

Diagnosis of spontaneous perforation

The clinical history is usually of severe pain in the chest or upper abdomen following a meal or a bout of drinking. Associated shortness of breath is common. Many cases are misdiagnosed as myocardial infarction, perforated peptic ulcer or pancreatitis if the pain is confined to the upper abdomen. There may be a surprising amount of rigidity on examination of the upper abdomen, even in the absence of any peritoneal contamination.

The diagnosis can usually be suspected from the history and associated clinical features. A chest x-ray is often confirmatory with air in the mediastinum, pleura or peritoneum. Pleural effusion occurs rapidly either as a result of free communication with the pleural space or as a reaction to adjacent inflammation in the mediastinum. A contrast swallow or CT is nearly always required to guide management (Figure 62.10).

Pathological perforation

Free perforation of ulcers or tumours of the oesophagus into the pleural space is rare. Erosion into an adjacent structure with fistula formation is more common. Aerodigestive fistula is most common and usually encountered in primary malignant disease of the oesophagus or bronchus. Coughing on eating and signs of

Figure 62.10 Computed tomography scan showing the site of perforation in the lower oesophagus.

aspiration pneumonitis may allow the problem to be recognised at a time when intervention may be appropriate and feasible. Covering the communication with a self-expanding metal stent is the usual solution. Erosion into a major vascular structure is invariably fatal.

Penetrating injury

Perforation by knives and bullets is uncommon, even in war, as the oesophagus is a relatively small target surrounded by other vital organs.

Foreign bodies

The oesophagus may be perforated during removal of a foreign body but, occasionally, an object that has been left in the oesophagus for several days will erode through the wall.

Instrumental perforation

Instrumentation is by far the most common cause of perforation. Modern instrumentation is remarkably safe, but perforation remains a risk that should never be forgotten (Summary box 62.4).

Summary box 62.4

Instrumental perforation

- Prevention of perforation is better than cure

Perforation related to diagnostic upper gastrointestinal endoscopy is unusual with an estimated frequency of about 1:4000 examinations. Perforation can occur in the pharynx or oesophagus, usually at sites of pathology or when the endoscope is passed blindly. A number of patient-related factors are associated with increased risk, including large anterior cervical osteophytes, the presence of a pharyngeal pouch and mechanical causes of obstruction. Perforation may follow biopsy of a malignant tumour.

Patients undergoing therapeutic endoscopy have a perforation risk that is at least ten times greater than those undergoing diagnostic endoscopy. The oesophagus may be perforated by guidewires, graduated dilators or balloons, or during the placement of self-expanding stents. The risk is considerably higher in patients with malignancy.

Diagnosis of instrumental perforation

In most cases, a combination of technical difficulties and an interventional procedure should lead to a high index of suspicion. History and physical signs may be useful pointers to the site of perforation.

Cervical perforation may result in pain localised to the neck, hoarseness, painful neck movements and subcutaneous emphysema. Intrathoracic and intra-abdominal perforations, which are more common, can give rise to immediate symptoms and signs either during or at the end of the procedure, including chest pain, haemodynamic instability, oxygen desaturation or visual evidence of perforation. Within the first 24 hours, patients may additionally complain of abdominal pain or respiratory difficulties. There may be evidence of subcutaneous emphysema, pneumothorax or hydropneumothorax. In some patients, the diagnosis may be missed and recognised only at a late stage

beyond 24 hours, as unexplained pyrexia, systemic sepsis or the development of a clinical fistula.

Prompt and thorough investigation is the key to management. Careful endoscopic assessment at the end of any procedure combined with a chest x-ray will identify many cases of perforation immediately. If not recognised immediately, then early and late suspected perforations should be assessed by a water-soluble contrast swallow. If this is negative, a dilute barium swallow should be considered. A CT scan can be used to replace a contrast swallow or as an adjunct to accurately delineate specific fluid collections.

Treatment of oesophageal perforations

Perforation of the oesophagus usually leads to mediastinitis. The loose areolar tissues of the posterior mediastinum allow a rapid spread of gastrointestinal contents. The aim of treatment is to limit mediastinal contamination and prevent or deal with infection. Operative repair deals with the injury directly, but imposes risks of its own; non-operative treatment aims to limit the effects of mediastinitis and provide an environment in which healing can take place.

The decision between operative and non-operative management rests on four factors. These are:

- 1 the site of the perforation (cervical versus thoracoabdominal oesophagus);
- 2 the event causing the perforation (spontaneous versus instrumental);
- 3 underlying pathology (benign or malignant);
- 4 the status of the oesophagus before the perforation (fasted and empty versus obstructed with a stagnant residue).

It follows that most perforations that can be managed non-operatively occur in the context of small instrumental perforations of a clean oesophagus without obstruction, where leakage is likely to be confined to the nearby mediastinum at worst (Table 62.1).

Table 62.1 Management options in perforation of the oesophagus.

Factors that favour non-operative management	Factors that favour operative repair
Small septic load	Large septic load
Minimal cardiovascular upset	Septic shock
Perforation confined to mediastinum	Pleura breached
Perforation by flexible endoscope	Boerhaave's syndrome
Perforation of cervical oesophagus	Perforation of abdominal oesophagus

Instrumental perforations in the cervical oesophagus are usually small and can nearly always be managed conservatively. The development of a local abscess is an indication for cervical drainage preventing the extension of sepsis into the mediastinum.

The conservative management of an instrumental perforation in the thoracoabdominal parts of the oesophagus can be undertaken when the perforation is detected early and prior to oral alimentation. General guidelines for non-operative management include:

- pain that is readily controlled with opiates;
- absence of crepitus, diffuse mediastinal gas, hydropneumothorax or pneumoperitoneum;
- mediastinal containment of the perforation with no evidence of widespread extravasation of contrast material;
- no evidence of ongoing luminal obstruction or a retained foreign body.

In addition, conservative management might be appropriate in patients who have remained clinically stable despite diagnostic delay. The principles of non-interventional management involve hyperalimentation, preferably by an enteral route, nasogastric suction and broad-spectrum intravenous antibiotics.

Surgical management is required whenever patients:

- are unstable with sepsis or shock;
- have evidence of a heavily contaminated mediastinum, pleural space or peritoneum;
- have widespread intrapleural or intraperitoneal extravasation of contrast material.

Ongoing luminal obstruction (often related to malignancy) in a frail patient considered unfit for major surgery can be dealt with by placement of a covered self-expanding stent. Expanding metal stents should be used with caution in patients with benign disease as they cause significant tissue reaction and some designs are impossible to remove at a later date. Biodegradable and removable stents are being developed and may be used alone or as a bridge to later definitive treatment where perforation accompanies obstruction.

For patients requiring surgery, the choice rests between direct repair, the deliberate creation of an external fistula or, rarely, oesophageal resection with a view to delayed reconstruction. Direct repair is preferred by many surgeons if the perforation is recognised early (within the first 4–6 hours) and the extent of mediastinal and pleural contamination is small. After 12 hours, the tissues become swollen and friable and less suitable for direct suture. The hole in the mucosa is always bigger than the hole in the muscle, and the muscle should be incised to see the mucosal edges clearly. It is essential that there should be no obstruction distal to the repair. A variety of local tissues (gastric fundus, pericardium, intercostal muscle) have been used to buttress such repairs.

Primary repair is inadvisable with late presentation and in the presence of widespread mediastinal and pleural contamination. These patients tend to be more ill as a result of the delay, and the aim of treatment should be to achieve wide drainage with the creation of a controlled fistula and distal enteral feeding. This can usually be achieved by placing a T-tube into the oesophagus along with appropriately located drains and a feeding jejunostomy. In unusual circumstances, for instance with extensive necrosis following corrosive ingestion, emergency oesophagectomy may be necessary. Oesophagostomy and gastrostomy should be performed with a view to delayed reconstruction.

MALLORY–WEISS SYNDROME

Forceful vomiting may produce a mucosal tear at the cardia rather than a full perforation. The mechanism of injury is different. In Boerhaave's syndrome, vomiting occurs against a closed glottis, and pressure builds up in the oesophagus. In Mallory–Weiss syndrome, vigorous vomiting produces a vertical split in

the gastric mucosa, immediately below the squamocolumnar junction at the cardia in 90 per cent of cases. In only 10 per cent is the tear in the oesophagus (Figure 62.11). The condition presents with haematemesis. Usually, the bleeding is not severe, but endoscopic injection therapy may be required for the occasional, severe case. Surgery is rarely required. There are two other injuries to the oesophagus that lie within the spectrum of the mucosal tear of Mallory–Weiss and the full-thickness tear of Boerhaave. Intramural rupture produces a dissection within the oesophageal wall that causes severe chest pain, often with odynophagia. It is best diagnosed by contrast radiology. Intramural haematoma is seen most often in elderly patients on anticoagulants or patients with coagulation disorders, and usually follows an episode of vomiting. Large haematomas causing dysphagia can occur extending from the cardia up to the carina. The diagnosis is readily made on endoscopy. Both intramural rupture and intramural haematoma can be managed conservatively. Symptoms usually resolve in 7–14 days, and oral intake can be reinstituted as soon as symptoms allow.

Figure 62.11 The endoscopic appearance of a mucosal tear at the cardia (Mallory–Weiss).

CORROSIVE INJURY

Corrosives such as sodium hydroxide (lye, caustic soda) or sulphuric acid may be taken in attempted suicide. Accidental ingestion occurs in children and when corrosives are stored in bottles labelled as beverages. All can cause severe damage to the mouth, pharynx, larynx, oesophagus and stomach. The type of agent, its concentration and the volume ingested largely determine the extent of damage. In general, alkalis are relatively odourless and tasteless, making them more likely to be ingested in large volume. Alkalis cause liquefaction, saponification of fats, dehydration and thrombosis of blood vessels that usually leads to fibrous scarring. Acids cause coagulative necrosis with eschar formation, and this coagulant may limit penetration to deeper layers of the oesophageal wall. Acids also cause more gastric damage than alkalis because of the induction of intense pylorospasm with pooling in the antrum.

Symptoms and signs are notoriously unreliable in predicting the severity of injury. The key to management is early endoscopy by an experienced endoscopist to inspect the whole of the oesophagus and stomach (Figure 62.12). Deep ulcers and the recognition of a grey or black eschar signify the most severe lesions with the greatest risk of perforation. Minor injuries with only oedema of the mucosa resolve rapidly with no late sequelae. These patients can safely be fed. With more severe injuries, a feeding jejunostomy may be appropriate until the patient

Figure 62.12 Acute caustic burn in the haemorrhagic phase.

can swallow saliva satisfactorily. The widespread use of broad-spectrum antibiotics and steroids is not supported by evidence.

Regular endoscopic examinations are the best way to assess stricture development (Figure 62.13). Significant stricture formation occurs in about 50 per cent of patients with extensive mucosal damage (Figure 62.14). The role and timing of repeat endoscopies with or without dilatation in such patients remains controversial. Other than the need for emergency surgery for bleeding or perforation, elective oesophageal resection should be deferred for at least three months until the fibrotic phase is established. Oesophageal replacement is usually required for very long or multiple strictures. Resection can be difficult because of perioesophageal inflammation in these patients. Because of associated gastric damage, colon may have to be used as the replacement conduit.

There is also controversy regarding the risk of developing carcinoma in the damaged oesophagus and stomach and how this might influence management. The lifetime risk is certainly less than 5 per cent. Some surgeons advocate resection and replacement, while others believe that oesophageal bypass and endoscopic surveillance is preferable, as removal of the badly damaged oesophagus from a scarred mediastinum can be hazardous (Summary box 62.5).

Summary box 62.5

Corrosive injury

- Skilled early endoscopy is mandatory

Figure 62.13 The late result of a caustic alkali burn with a high oesophageal stricture.

Figure 62.14 Caustic or lye stricture with marked stenosis high in the body of the oesophagus. The strictures are frequently multiple and difficult to dilate unless treated energetically at an early stage.

DRUG-INDUCED INJURY

Many medications, such as antibiotics and potassium preparations, are potentially damaging to the oesophagus, as tablets may remain for a long time, especially if taken without an adequate drink. Acute injury presents with dysphagia and odynophagia, which may be severe. The inflammation usually resolves within 2–3 weeks, and no specific treatment is required apart from appropriate nutritional support. A stricture may follow.

GASTRO-OESOPHAGEAL REFLUX DISEASE

Aetiology

Normal competence of the gastro-oesophageal junction is maintained by the LOS. This is influenced by both its physiological function and its anatomical location relative to the diaphragm and the oesophageal hiatus. In normal circumstances, the LOS transiently relaxes as a coordinated part of swallowing, as a means of allowing vomiting to occur and in response to stretching of the gastric fundus, particularly after a meal to allow swallowed air to be vented. Most episodes of physiological reflux occur during postprandial transient lower oesophageal sphincter relaxations (TLOSRS). In the early stages of GORD, most pathological reflux occurs as a result of an increased number of

TLOSRS rather than a persistent fall in overall sphincter pressure. In more severe GORD, LOS pressure tends to be generally low, and this loss of sphincter function seems to be made worse if there is loss of an adequate length of intra-abdominal oesophagus.

The absence of an intra-abdominal length of oesophagus results in a sliding hiatus hernia. The normal condensation of peritoneal fascia over the lower oesophagus (the phreno-oesophageal ligament) is weak, and the crural opening widens allowing the upper stomach to slide up through the hiatus. The loss of the normal anatomical configuration exacerbates reflux, although sliding hiatus hernia alone should not be viewed as the cause of reflux. Sliding hiatus hernia is associated with GORD and may make it worse but, as long as the LOS remains competent, pathological GORD does not occur. Many GORD sufferers do not have a hernia, and many of those with a hernia do not have GORD. It should be noted that rolling or paraoesophageal hiatus hernia is a quite different and potentially dangerous condition (see under Paraoesophageal ('rolling') hiatus hernia below). A proportion of patients have a rolling hernia and symptomatic GORD or a mixed hernia with both sliding and rolling components. Reflux oesophagitis that is visible endoscopically is a complication of GORD and occurs in a minority of sufferers overall, but in around 40 per cent of patients referred to hospital.

In Western societies, GORD is the most common condition affecting the upper gastrointestinal tract. This is partly due to the declining incidence of peptic ulcer as the incidence of infection with *Helicobacter pylori* has reduced as a result of improved socio-economic conditions along with a rising incidence of GORD in the last 20–30 years. The cause of the increase is unclear, but may be due in part to increasing obesity. The strong association between GORD, obesity and the parallel rise in the incidence of adenocarcinoma of the oesophagus represents a major health challenge for most Western countries.

Clinical features

The classical triad of symptoms is retrosternal burning pain (heartburn), epigastric pain (sometimes radiating through to the back) and regurgitation. Most patients do not experience all three. Symptoms are often provoked by food, particularly those that delay gastric emptying (e.g. fats, spicy foods). As the condition becomes more severe, gastric juice may reflux to the mouth and produce an unpleasant taste often described as 'acid' or 'bitter'. Heartburn and regurgitation can be brought on by stooping or exercise. A proportion of patients have odynophagia with hot beverages, citrus drinks or alcohol. Patients with nocturnal reflux and those who reflux food to the mouth nearly always have severe GORD. Some patients present with less typical symptoms such as angina-like chest pain, pulmonary or laryngeal symptoms. Dysphagia is usually a sign that a stricture has occurred, but may be caused by an associated motility disorder.

Because GORD is such a common disorder, it should always be the first thought when a patient presents with oesophageal symptoms that are unusual or that defy diagnosis after a series of investigations.

Diagnosis

In most cases, the diagnosis is assumed rather than proven, and treatment is empirical. Investigation is only required when the diagnosis is in doubt, when the patient does not respond to a proton pump inhibitor (PPI) or if dysphagia is present. The

most appropriate examination is endoscopy with biopsy. If the typical appearance of reflux oesophagitis, peptic stricture or Barrett's oesophagus is seen, the diagnosis is clinched, but visible oesophagitis is not always present, even in patients selected as above. This is compounded in clinical practice by the widespread use of PPIs, which cause rapid healing of early mucosal lesions. Many patients will have received such treatment before referral. The endoscopic appearances of the normal oesophagus, hiatus hernia, oesophagitis and stricture are shown in Figures 62.15, 62.16, 62.17, 62.18, 62.19, 62.20 and 62.21. It is worth remembering that the correlation between symptoms and endoscopic appearances is poor. On the other hand, there is a strong correlation between worsening endoscopic appearances and the duration of oesophageal acidification on pH testing.

In patients with atypical or persistent symptoms despite therapy, oesophageal manometry and 24-hour oesophageal pH recording (ideally with impedance measurement) may be justified to establish the diagnosis and guide management (Summary box 62.6).

Summary box 62.6

Diagnostic measurement in GORD

- 24-hour pH recording is the 'gold standard' for diagnosis of GORD
- TLOSRS are the most important manometric findings in GORD
- The length and pressure of the LOS are also important

As a matter of routine, PPIs are stopped 1 week before oesophageal pH recording, but acid secretion is sometimes reduced for 2 weeks or more, and this can necessitate repeat examination after a prolonged interval without a PPI. Manometry and pH recording are essential in patients being considered for antireflux surgery. While the main purpose of the test is objectively to quantify the extent of reflux disease, it is also used to rule out a diagnosis of achalasia. In the early stages of achalasia, chest pain can dominate the clinical picture and, when associated with

Figure 62.15 The endoscopic appearance of the normal squamous mucosa in the body of the oesophagus.

Figure 62.17 The squamocolumnar junction is clearly seen in the lower oesophagus with a normal sharp demarcation.

intermittent swallowing problems and non-specific symptoms, it is easy to see how a clinical diagnosis of GORD might be made. Patients with achalasia can also have an abnormal pH study as a result of fermentation of food residue in a dilated oesophagus. Usually, the form of the pH trace is different from that of GORD, with slow undulations of pH rather than rapid bursts of reflux, but the complete absence of peristalsis on manometry is pathognomonic of achalasia.

Figure 62.18 Sliding hiatus hernia. The diaphragm can be seen constricting the upper stomach.

Barium swallow and meal examination gives the best appreciation of gastro-oesophageal anatomy (Figure 62.22). This may be important in the context of surgery for rolling or mixed hiatus hernias, but it is unimportant in most patients with GORD.

Management of uncomplicated GORD

Medical management

Most sufferers from GORD do not consult a doctor and do not need to do so. They self-medicate with over-the-counter medicines such as simple antacids, antacid-alginate preparations and H₂-receptor antagonists. Consultation is more likely when symptoms are severe, prolonged and unresponsive to the above treatments. Simple measures that are often neglected include advice about weight loss, smoking, excessive consumption of alcohol, tea or coffee, the avoidance of large meals late at night and a modest degree of head-up tilt of the bed. Tilting the bed has been shown to have an effect that is similar to taking an H₂-receptor antagonist. The common practice of using additional pillows has no significant effect.

PPIs are the most effective drug treatment for GORD. Indeed, they are so effective that, once started, patients are very reluctant to stop taking them. Given an adequate dose for 8 weeks, most patients have a rapid improvement in symptoms (within a few days), and more than 90 per cent can expect full mucosal healing at the end of this time. For this reason, a policy of 'step-down' medical treatment is advocated based on the general advice outlined above and a standard dose of a PPI given for 8 weeks. At the end of that time, the dose of PPI is reduced to that which keeps the patient free of symptoms, and this might even mean the cessation of PPI treatment. Because most patients do not make major lifestyle changes and because PPIs are so effective, many remain on long-term treatment. For the minority who do not respond adequately to a standard dose, a trial at an increased dose or the addition of an H₂-receptor antagonist is recommended. If unsuccessful, these patients should be formally investigated.

Proton pump inhibitor therapy is also important in patients with reflux-induced strictures, resulting in significant prolongation of the intervals between endoscopic dilatation. As yet, fears that chronic acid suppression might have serious long-term side effects including the risk of gastric cancer seem unwarranted.

Surgery

Strictly speaking, the need for surgery should have been reduced as medication has improved so much. Paradoxically, the number of antireflux operations has remained relatively constant and may even be increasing. This is probably due partly to increased patient expectations and partly to the advent of minimal access surgery, which has improved the acceptability of procedures.

Endoscopic treatments

A number of endoscopic treatments have been tried in the last ten years that attempt to augment a failing LOS. These involve endoscopic suturing devices that plicate gastric mucosa just below the cardia to accentuate the angle of His, radiofrequency ablation applied to the level of the sphincter and the injection of submucosal polymers into the lower oesophagus. The procedures have generally been applied to patients with only small hiatus hernias or none at all, so only a small proportion of patients who present to hospitals are suitable. While all

Figure 62.22 (a) Sliding hiatus hernia with a sphincter and diaphragmatic crural narrowing clearly shown. (b) Another sliding hernia in which the sphincter is lax, and the diaphragm is wide open. The patient is in the Trendelenburg position to demonstrate barium in the fundus. This unphysiological position may stimulate 'reflux' in those who do not have gastro-oesophageal reflux disease (GORD).

methods produce some temporary improvement in symptoms and objective assessments of reflux, failure rates at one year are over 50 per cent, and there are no large case series that have reported long-term outcomes.

Surgical treatments

The indication for surgery in uncomplicated GORD is

essentially patient choice. The risks and possible benefits need to be discussed in detail. Risks include a small mortality rate (0.1–0.5 per cent, depending on patient selection), failed operation (5–10 per cent) and side effects such as dysphagia, gas bloat or abdominal discomfort (10 per cent). With current operative techniques, 85–90 per cent of patients should be satisfied with the result of an antireflux operation. Patients who are asymptomatic on a PPI need a careful discussion of the risk side of the equation. Those who are symptomatic on a PPI need a careful clinical review to make sure that they will benefit from an operation. Reasons for failure on a PPI include 'volume' reflux (a good indication for surgery), a 'hermit' lifestyle in which the least deviation from lifestyle rules leads to symptoms (a good indication), psychological distress with intolerance of minor symptoms (a poor indication; these patients are likely to be dissatisfied with surgery), poor compliance (a good indication if the reason for poor compliance is the side effects of treatment, otherwise a bad indication) and misdiagnosis of GORD.

Which operation?

There are many operations for GORD, but they are virtually all based on the creation of an intra-abdominal segment of oesophagus, crural repair and some form of wrap of the upper stomach (fundoplication) around the intra-abdominal oesophagus. The contribution of each component to operative success is widely debated, but it is clear that operations that fail to address all three components have inferior success rates. The major types of antireflux operation were all developed in the 1950s (Figure 62.23). When performed correctly, these are all effective operations. Randomised clinical trials do not show a clear advantage for any one operation over the others. One meta-analysis, however, has come down in favour of the Toupet posterior partial fundoplication over the Nissen total fundoplication when performed laparoscopically.

Figure 62.23 Various operations for the surgical correction of gastro-oesophageal reflux disease. (a) The original Allison repair of hiatus hernia (this is ineffective and is no longer done); (b) Nissen fundoplication; (c) Hill procedure; (d) Belsey mark IV operation.

Total fundoplication (Nissen) tends to be associated with slightly more short-term dysphagia but is the most durable repair in terms of long-term reflux control. Partial fundoplication, whether performed posteriorly (Toupet) or anteriorly (Dor, Watson), has fewer short-term side effects, although this is sometimes at the expense of a slightly higher long-term failure rate. One disadvantage of total fundoplication is the creation of an overcompetent cardia, resulting in the 'gas bloat' syndrome in which belching is impossible. The stomach fills with air, the patient feels very full after small meals and passes excessive flatus. This does not seem to occur with partial fundoplication. The problem has been largely overcome by the 'floppy' Nissen technique in which the fundoplication is loose around the oesophagus and is kept short in length. While the other short-term side effects of fundoplication usually resolve within three months of surgery, this is rarely the case for gas bloat. The problem is best remedied by conversion to a partial fundoplication.

As with primary surgery, a variety of revisional procedures have been described. For most patients, recurrent reflux relates to anatomical failure, so the solution is a revisional fundoplication. A very small proportion of patients may undergo more than two operations to correct recurrent reflux or unacceptable side effects. Revisional surgery carries a lower chance of success and, in some patients, local revision is technically impossible. The final resort is partial gastrectomy with a Roux-en-Y reconstruction. This reduces gastric acid secretion and diverts bile and pancreatic secretions away from the stomach. Thus, the volume of potential refluxate in the stomach is reduced and, because of its changed composition, it is less damaging to the oesophagus.

For many years, the relative merits of thoracic and abdominal approaches were hotly debated. The introduction of minimal access surgery has made this debate practically obsolete, and most antireflux operations are now done with a laparoscopic approach.

Laparoscopic fundoplication

Five cannulae are inserted in the upper abdomen (Figure 62.24). The cardia and lower oesophagus are separated from the diaphragmatic hiatus. An appropriate length of oesophagus is mobilised in the mediastinum. The fundus may be mobilised by dividing the short gastric vessels that tether the fundus to the spleen. The hiatus is narrowed by sutures placed behind the oesophagus. In total (Nissen) fundoplication, the fundus is drawn behind the oesophagus and then sutured to itself in front of the oesophagus (Figure 62.25a). In partial fundoplication, the fundus is drawn either behind or in front of the oesophagus and sutured to it on each side, leaving a strip of exposed oesophagus either at the front (Figure 62.25b) or at the back.

Complications of gastro-oesophageal reflux disease

Stricture

Reflux-induced strictures (see Figure 62.21) occur mainly in the late middle-aged and the elderly, but they may present in children. It is important to distinguish a benign reflux-induced stricture from a carcinoma. This is not usually difficult on the basis of location (immediately above the oesophagogastric junction), length (only about 1–2 cm) and smooth mucosa, but sometimes

Rudolph Nissen, 1896–1981, Professor of Surgery, Istanbul, Turkey, and later at Basle, Switzerland.

a cancer spreads under the oesophageal mucosa at its upper margin, producing a benign-looking stricture.

Peptic strictures generally respond well to dilatation and long-term treatment with a PPI. As most patients are elderly, antireflux surgery is not usually considered. However, it is an alternative to long-term PPI treatment, just as in uncomplicated GORD in younger and fitter patients. Most patients do not require anything other than a standard operation (Summary box 62.7).

Summary box 62.7

Peptic stricture

- Day-case dilatation and PPI for peptic stricture

Oesophageal shortening

The issue of oesophageal shortening continues to provoke debate. There can be no doubt that, in the presence of a large sliding hiatus hernia, the oesophagus is short, but this does not necessarily mean that, with mobilisation from the mediastinum, it cannot easily be restored to its normal length. The extent to which severe inflammation in the wall of the oesophagus causes fibrosis and real shortening is less clear. If a good segment of intra-abdominal oesophagus cannot be restored without tension, a Collis gastroplasty should be performed (Figure 62.26). This produces a neo-oesophagus around which a fundoplication can be done (Collis–Nissen operation) (Summary box 62.8).

Figure 62.25 (a) Total (Nissen) fundoplication; (b) partial fundoplication (Toupet).

Summary box 62.8

GORD

- Is due to loss of competence of the LOS and is extremely common
- May be associated with a hiatus hernia, which may be sliding or, less commonly, rolling (paraoesophageal)
- The most common symptoms are heartburn, epigastric discomfort and regurgitation, often made worse by stooping and lying
- Achalasia and GORD are diagnostically easily confused
 - Dysphagia may occur, but a neoplasm must be excluded
 - Diagnosis and treatment can be instituted on clinical grounds
- Endoscopy may be required and 24-hour pH is the 'gold standard'

Management is primarily medical (PPIs being the most effective), but surgery may be required; laparoscopic fundoplication is the most popular technique
Stricture may develop in time

Barrett's oesophagus (columnar-lined lower oesophagus)

Barrett's oesophagus is a metaplastic change in the lining mucosa of the oesophagus in response to chronic gastro-oesophageal reflux (Figure 62.27). Many of these patients do not have particularly severe symptoms, although they do have the most abnormal pH profiles. This adaptive response involves a mosaic of cell types, probably beginning as a simple columnar epithelium that becomes 'specialised' with time. The hallmark of 'specialised' Barrett's epithelium is the presence of mucus-secreting goblet cells (intestinal metaplasia). One of the great mysteries of GORD is why some people develop oesophagitis and others develop Barrett's oesophagus, often without significant oesophagitis. In Barrett's oesophagus, the junction between squamous oesophageal mucosa and gastric mucosa moves proximally. It may be difficult to distinguish a Barrett's oesophagus from a tubular, sliding hiatus hernia during endoscopy, as the two often coexist (Figure 62.28) or where the visible Barrett's segment is very short. The key is where the gastric mucosal folds end. The mucosa in the body of the stomach has longitudinal

Figure 62.26 Collis gastroplasty to produce a neo-oesophagus around which a Nissen fundoplication is done. The operation may be performed by a laparoscopic as well as an open approach using circular and linear staplers.

Figure 62.27 Barrett's oesophagus with proximal migration of the squamocolumnar junction (a) and with a view of the distal oesophagus (b).

folds; the columnar lining of Barrett's oesophagus is smooth. Strictures can occur in Barrett's oesophagus and nearly always appear at the new squamocolumnar junction (Figure 62.29). Rarely, a stricture may occur in the columnar segment after healing of a Barrett's ulcer (Figure 62.30). When intestinal metaplasia occurs, there is an increased risk of adenocarcinoma of the oesophagus (Summary box 62.9), which is about 25 times that of the general population (Figures 62.30, 62.31 and 62.32).

Patients who are found to have Barrett's oesophagus may be submitted to regular surveillance endoscopy with multiple biopsies in the hope of finding dysplasia or *in situ* cancer rather than allowing invasive cancer to develop and cause symptoms. There

Figure 62.29 The radiological appearance of a mid-oesophageal stricture in a patient with Barrett's oesophagus (a) and in a patient with a normal lumen following dilatation (b).

Summary box 62.9**Barrett's oesophagus**

- Intestinal metaplasia is an important risk factor for the development of adenocarcinoma
- Do not confuse Barrett's ulcer with oesophagitis

is as yet no general agreement about the benefits of surveillance endoscopy, nor about its ideal frequency. Annual endoscopy has been widely practised, but two-year intervals are probably adequate, provided no dysplasia has been detected. A significant problem is that the incidence of Barrett's oesophagus in the community is estimated to be at least ten times the incidence discovered in dyspeptic patients referred for endoscopy. Thus, adenocarcinoma in Barrett's oesophagus often presents with invasive cancer without any preceding reflux symptoms.

Until recently, Barrett's oesophagus was not diagnosed until there was at least 3 cm of columnar epithelium in the distal oesophagus. With the better appreciation of the importance of intestinal metaplasia, Barrett's oesophagus may be diagnosed if there is any intestinal metaplasia in the oesophagus. The relative risk of cancer probably increases with increasing length of abnormal mucosa. The following terms are widely used:

- classic Barrett's (3 cm or more columnar epithelium);
- short-segment Barrett's (less than 3 cm of columnar epithelium);
- cardia metaplasia (intestinal metaplasia at the oesophagogastric junction without any macroscopic change at endoscopy).

When Barrett's oesophagus is discovered, the treatment is that of the underlying GORD. There has been considerable interest in recent years in endoscopic methods of ablating Barrett's mucosa in the hope of eliminating the risk of cancer development. Laser, photodynamic therapy, argon-beam plasma coagulation and endoscopic mucosal resection (EMR) have all been used. In conjunction with high-dose PPI treatment or an antireflux operation, these endoscopic methods can result in a

neosquamous lining. There is no evidence yet that any of these methods is reliable in eliminating cancer risk. Residual islands of Barrett's epithelium can persist, glands may be buried beneath the new lining, and damage to the oesophageal wall may cause stricturing.

PARAOESOPHAGEAL ('ROLLING') HIATUS HERNIA

True paraoesophageal hernias in which the cardia remains in its normal anatomical position are rare. The vast majority of rolling hernias are mixed hernias in which the cardia is displaced into the chest and the greater curve of the stomach rolls into the mediastinum (Figure 62.33). Sometimes, the whole of the stomach lies in the chest (Figure 62.34). Colon or small intestine may sometimes lie in the hernia sac. The hernia is most common in the elderly, but may occur in young fit people. As the stomach rolls up into the chest, there is always an element of rotation (volvulus) (Summary box 62.10).

Summary box 62.10

'Rolling' hiatus hernia

- Potentially dangerous, because of volvulus

The symptoms of rolling hernia are mostly due to twisting and distortion of the oesophagus and stomach. Dysphagia is common. Chest pain may occur from distension of an obstructed stomach. Classically, the pain is relieved by a loud belch. Symptoms of GORD are variable. Strangulation, gastric perforation and gangrene can occur. Emergency presentation with any of these complications carries high mortality on account of a combination of late diagnosis, generally elderly patients with comorbid diseases and the complexity of surgery involved.

The hernia may be visible on a plain radiograph of the chest as a gas bubble, often with a fluid level behind the heart (Figure 62.35). A barium meal is the best method of diagnosis. The endoscopic appearances may be confusing, especially in large hernias when it is easy to become disorientated.

Symptomatic rolling hernias nearly always require surgical repair as they are potentially dangerous. The risk of an asymptomatic patient developing a significant problem when a rolling hiatus hernia is discovered incidentally has probably been overestimated in the past. The annual risk is probably no more than 1 per cent. Patients who present as an emergency with acute chest pain may be treated initially by nasogastric tube to relieve the distension that causes the pain, followed by operative repair. If the pain is not relieved or perforation is suspected, immediate operation is mandatory.

Figure 62.34 A huge paraoesophageal hernia with an upside-down stomach and the pylorus just below the hiatus.

Emergency surgery needs to be tailored to the problem encountered and the fitness of the patient. Elective surgery involves reduction of the hernia, excision of the sac, reducing the crural defect and some form of retention of the stomach in the abdomen. Some surgeons perform a fundoplication, arguing that this is a very effective means of maintaining reduction and that it deals with the associated GORD. Others argue that fundoplication should only be done if reflux can be conclusively demonstrated beforehand. Surprisingly, both philosophies achieve good results. Laparoscopic repair has recently become popular. Full anatomical repair of a large rolling hernia can be difficult by this approach and requires considerable expertise. Secure closure of the hiatal defect can be a problem, and some surgeons advocate mesh to reinforce the repair.

NEOPLASMS OF THE OESOPHAGUS

Benign tumours

Benign tumours of the oesophagus are relatively rare. True papillomas, adenomas and hyperplastic polyps do occur, but the majority of 'benign' tumours are not epithelial in origin and arise from other layers of the oesophageal wall (gastrointestinal stromal tumour (GIST), lipoma, granular cell tumour). Most benign oesophageal tumours are small and asymptomatic, and even a large benign tumour may cause only mild symptoms (Figure 62.36). The most important point in their management is usually to carry out an adequate number of biopsies to prove beyond reasonable doubt that the lesion is not malignant (Figure 62.37).

Malignant tumours

Non-epithelial primary malignancies are also rare, as is malignant melanoma. Secondary malignancies rarely involve the oesophagus with the exception of bronchogenic carcinoma by direct invasion of either the primary and/or contiguous lymph nodes.

Carcinoma of the oesophagus

Cancer of the oesophagus is the sixth most common cancer in the world. In general, it is a disease of mid to late adulthood, with a poor survival rate. Only 5–10 per cent of those diagnosed will survive for five years (Summary box 62.11).

Summary box 62.11

Carcinoma of the oesophagus

- Squamous cell usually affects the upper two-thirds; adenocarcinoma usually affects the lower-third
- Common aetiological factors are tobacco and alcohol (squamous cell) and GORD (adenocarcinoma)
- The incidence of adenocarcinoma is increasing
- Lymph node involvement is a bad prognostic factor
- Dysphagia is the most common presenting symptom, but is a late feature
- Accurate pretreatment staging is essential in patients thought to be fit to undergo 'curative' treatment

Pathology and aetiology

Squamous cell cancer (Figures 62.38 and 62.39) and adenocarcinoma (Figures 62.40 and 62.41) are the most common types. Squamous cell carcinoma generally affects the upper two-thirds of the oesophagus and adenocarcinoma the lower one-third. Worldwide, squamous cell cancer is most common, but adenocarcinoma predominates in the West and is increasing in incidence.

Geographical variation in oesophageal cancer

The incidence of oesophageal cancer varies more than that of any other cancer. Squamous cell cancer is endemic in the

Figure 62.36 Classic appearance of a large oesophageal gastrointestinal stromal tumour on barium swallow.

Figure 62.37 An intraluminal polyp that proved to be a leiomyosarcoma.

Figure 62.38 The classic appearances of a mid-oesophageal proliferative squamous cell carcinoma.

Transkei region of South Africa and in the Asian 'cancer belt' that extends across the middle of Asia from the shores of the Caspian Sea (in northern Iran) to China. The highest incidence in the world is in Linxian in Henan province in China, where it is the most common single cause of death, with more than 100 cases per 100 000 population per annum. The cause of the disease in the endemic areas is not known, but it is probably due to a combination of fungal contamination of food and nutritional deficiencies. In Linxian, supplementation of the diet with beta-carotene, vitamin E and selenium has been shown to reduce the incidence.

Away from the endemic areas, tobacco and alcohol are major factors in the occurrence of squamous cancer. Incidence rates vary from less than 5:100 000 in white people in the US to 26.5:100 000 in some regions of France.

In many Western countries, the incidence of squamous cell cancer has fallen or remained static, but the incidence of adenocarcinoma of the oesophagus has increased dramatically since the mid-1970s at a rate of 5–10 per cent per annum. The change is greater than that of any other neoplasm in this time. Adenocarcinoma now accounts for 60–75 per cent of all oesophageal cancers in several countries. The reason for this change is not understood. A similar rate of increase in GORD over the same period, which mirrors an increase in obesity in the West, is likely to be an important factor, particularly through the link to Barrett's oesophagus. There has been a similar increase in the incidence of carcinoma of the cardia of the stomach, which suggests that cancer of the cardia and adenocarcinoma of the oesophagus may share common aetiological factors. With a fall-

Figure 62.39 Squamous cell carcinoma of the oesophagus producing an irregular stricture with shouldered margins.

ing incidence of cancer in the rest of the stomach, more than 60 per cent of all upper gastrointestinal cancers in the West involve the cardia or distal oesophagus.

Both adenocarcinomas and squamous cell carcinomas tend to disseminate early. Sadly, the classical presenting symptoms of dysphagia, regurgitation and weight loss are often absent until the primary tumour has become advanced, and so the tumour is often well established before the diagnosis is made. Tumours can spread in three ways: invasion directly through the oesophageal wall, via lymphatics or in the bloodstream. Direct spread occurs both laterally, through the component layers of the oesophageal wall, and longitudinally within the oesophageal wall. Longitudinal spread is mainly via the submucosal lymphatic channels of the oesophagus. The pattern of lymphatic drainage is therefore not segmental, as in other parts of the gastrointestinal tract. Consequently, the length of oesophagus involved by tumour is frequently much longer than the macroscopic length of the malignancy at the epithelial surface. Lymph node spread occurs commonly. Although the direction of spread to regional lymphatics is predominantly caudal, the involvement of lymph nodes is potentially widespread and can also occur in a cranial direction. Any regional lymph node from the superior mediastinum to the coeliac axis and lesser curve of the stomach may be involved regardless of the location of the primary lesion within the oesophagus. Haematogenous spread may involve a

Figure 62.40 Adenocarcinoma of the lower oesophagus, spreading upwards from the cardia.

Figure 62.41 Computed tomography scan showing a primary tumour of the lower oesophagus.

variety of different organs including the liver, lungs, brain and bones. Tumours arising from the intra-abdominal portion of the oesophagus may also disseminate transperitoneally.

Clinical features

Most oesophageal neoplasms present with mechanical symptoms, principally dysphagia, but sometimes also regurgitation,

vomiting, odynophagia and weight loss. Clinical findings suggestive of advanced malignancy include recurrent laryngeal nerve palsy, Horner's syndrome, chronic spinal pain and diaphragmatic paralysis. Other factors making surgical cure unlikely include weight loss of more than 20 per cent and loss of appetite. Cutaneous tumour metastases or enlarged supraclavicular lymph nodes may be seen on clinical examination and indicate disseminated disease. Hoarseness due to recurrent laryngeal nerve palsy is a sign of advanced and incurable disease. Palpable lymphadenopathy in the neck is likewise a sign of advanced disease.

Patients with early disease may have non-specific dyspeptic symptoms or a vague feeling of 'something that is not quite right' during swallowing. Some are diagnosed during endoscopic surveillance of patients with Barrett's oesophagus and, while this does identify patients with the earliest stages of disease, such programmes have little overall impact, as most patients with Barrett's oesophagus are unknown to the medical profession and make their first presentation with a symptomatic and therefore usually locally advanced oesophageal cancer. The widespread use of endoscopy as a diagnostic tool does, nevertheless, provide an opportunity for early diagnosis (Figure 62.42). Biopsies should be taken of all lesions in the oesophagus (Figures 62.43 and 62.44), no matter how trivial they appear and irrespective of the indication for the examination.

Figure 62.42 Carcinoma *in situ* showing the varied presentations: (a) occult form; (b) erythroplakia; (c) leukoplakia. The right-hand pictures in (a) and (b) demonstrate the use of vital staining with methylene blue.

Figure 62.43 Endoscopic appearances of a mid-oesophageal squamous cell carcinoma.

Figure 62.44 Beware the differential diagnosis of infection, for what appears to be a tumour. This mid-oesophageal mass was actually tuberculosis.

Investigation

Endoscopy is the first-line investigation for most patients. It provides an unrivalled direct view of the oesophageal mucosa and any lesion allowing its site and size to be documented. Cytology and/or histology specimens taken via the endoscope are crucial for accurate diagnosis. The combination of histology and cytology increases the diagnostic accuracy to more than 95 per cent. The chief limitation of conventional endoscopy is that only the

mucosal surface can be studied and biopsied. Other investigations are therefore usually required to define the extent of local or distant spread. The improved image resolution of modern endoscopes and novel techniques involving magnification and the use of dyes to enhance surface detail may lead to more early lesions being recognised (see Figure 62.42).

General assessment and staging

Once the initial diagnosis of a malignant oesophageal neoplasm has been made, patients should be assessed first in terms of their general health and fitness for potential therapies. Their preferences should also be considered. Most potentially curative therapies include radical surgery, although chemoradiotherapy is an alternative in squamous cell carcinoma. Patients who are unfit for, or who do not wish to contemplate, radical treatments should not be investigated further, but should be diverted to appropriate palliative therapies, depending on symptoms and current quality of life. Only those patients suitable for potentially curative therapies should proceed to staging investigations to rule out haematogenous spread and then to assess locoregional stage (endoscopic ultrasound (EUS) \pm laparoscopy). This will distinguish between early (T1/T2, N0) and advanced lesions (T3/T4, N1) and indicate whether surgery alone or multimodal therapy is most appropriate. Where attempted cure is deemed possible, the aim should be to provide the best chance of cure while minimising perioperative risks. In general, surgery alone should be reserved for patients with early disease, and multimodal therapy should be used in patients with locally advanced disease, in whom the chance of cure by surgery alone is small (generally less than 20 per cent).

The most widely used pathological staging system is the World Health Organization (tumour–nodes–metastasis TNM) classification.

Table 62.2 shows the TNM system for oesophageal cancer in its most updated form. Like all pathological systems, it is reliant on the nature and extent of the surgery performed. For example, performing more extensive radical surgical lymphadenectomy provides a more accurate assessment of the 'N' stage. There is evidence that many patients described as N0 in the past were probably N1, a phenomenon described as stage migration.

Staging information may be gathered before the commencement of therapy (e.g. at open operation) or following treatment (histology or post-mortem). The techniques commonly used to provide preoperative staging data are described in Figure 62.45, along with a suggested algorithm.

Blood tests

These are of limited value. Blood tests reveal nothing about local invasion or regional lymph node spread and, to date, no reliable tumour marker for oesophageal cancer has been isolated from peripheral blood. The presence of abnormal liver function tests (LFTs) may suggest the presence of liver metastases, but this is generally too insensitive to be diagnostic. Many patients with known liver metastases have normal LFTs. At best, abnormal LFTs only reinforce the clinical suspicion of spread to the liver, and further imaging is usually required to confirm the diagnosis.

Transcutaneous ultrasound

It is difficult to visualise mediastinal structures with transcutaneous ultrasound. With the relatively low-frequency sound waves

Table 62.2 TNM staging scheme for oesophageal cancer.

Tis	High-grade dysplasia
T1	Tumour invading lamina propria or submucosa
T2	Tumour invading muscularis propria
T3	Tumour invading beyond muscularis propria
T4a	Tumour invading adjacent structures (pleura, pericardium, diaphragm)
T4b	Tumour invading adjacent structures (trachea, bone, aorta)
N0	No lymph node metastases
N1	Lymph node metastases in 1–2 nodes
N2	Lymph nodes metastases in 3–6 nodes
N3	Lymph node metastases in 7 or more lymph nodes
M0	No distant metastases
M1	All other distant metastases
Stage	1A: T1N0M0; 1B: T2N0M0; 2A: T3N0M0; 2B: T1/2N0M0; 3A: T4aN0M0, T3N1M0, T1/2N2M0; 3B: T3N2M0; 3C: T4aN1/2M0, T4bN0-3M0, T1-4N3M0; 4: T1-4N1-3M1

used, good depth of tissue penetration is achieved at the expense of poor image resolution. In addition, the mediastinal organs are surrounded by bone and air, which renders them largely inaccessible to external ultrasound. The technique is therefore used mainly to assess spread to the liver, the whole of which can be clearly visualised by standard transcutaneous ultrasound. Haematogenous spread can be more fully assessed by combining ultrasound with chest radiography, although this combination is less accurate than CT scanning.

Figure 62.45 Algorithm for the management of oesophageal cancer.

Bronchoscopy

Many middle- and upper-third oesophageal carcinomas (and therefore usually squamous carcinomas) are sufficiently advanced at the time of diagnosis that the trachea or bronchi are already involved (Figure 62.46). Bronchoscopy may reveal either impingement or invasion of the main airways in over 30 per cent of new patients with cancers in the upper third of the oesophagus. In some cases, therefore, bronchoscopy alone can confirm that the tumour is locally unresectable.

Laparoscopy

This is a useful technique for the diagnosis of intra-abdominal and hepatic metastases. It has the advantage of enabling tissue samples or peritoneal cytology to be obtained and is the only modality reliably able to detect peritoneal tumour seedlings (Figure 62.47). This is particularly important for tumours arising from the intra-abdominal portion of the oesophagus, cardia and where there is a potential communication between a full-thickness tumour and the peritoneal cavity, for instance where there is a hiatus hernia.

Figure 62.46 Invasion into the posterior wall of the trachea from an oesophageal carcinoma.

Figure 62.47 Adenocarcinoma of the cardia. Transcoelomic spread may occur with this type of lesion.

Computed tomography

Computed tomography scanning is the modality most used to identify haematogenous metastases (Figure 62.48). Distant organs are easily seen and metastases within them visualised with high accuracy (94–100 per cent). The normal thoracic oesophagus is easily demonstrated by CT scanning. The mediastinal fat planes are usually clearly imaged in healthy individuals, and any blurring or distortion of these images is a fairly reliable indicator of abnormality. In cachectic patients with dysphagia and malnutrition, the mediastinal fat plane may be virtually absent, making local invasion difficult to assess. Spiral and thin-slice CT permit structures such as lymph nodes to be adequately imaged, down to a minimum diameter of about 5 mm. Smaller nodes cannot be reliably visualised, and it is not possible to distinguish between enlarged lymph nodes that have reactive changes only and metastatic nodes. Similarly, micrometastases within normal-sized nodes cannot be detected.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) does not expose the patient to ionising radiation and needs no intravascular contrast medi-

um, although intraoesophageal air or contrast media may help to assess wall thickness. Distant metastases to organs such as the liver are usually reliably identified by MRI but, at the present time, there do not seem to be additional benefits over CT.

Endoscopic ultrasound

After haematogenous spread, the two principal prognostic factors for oesophageal cancer are the depth of tumour penetration through the oesophageal wall and regional lymph node spread. Although CT will detect distant metastasis, its limited axial resolution precludes a reliable assessment of both the depth of wall penetration and lymph node involvement. Endoscopic ultrasound can determine the depth of spread of a malignant tumour through the oesophageal wall (T1–3), the invasion of adjacent organs (T4) and metastasis to lymph nodes (N0 or N1) (Figures 62.49, 62.50 and 62.51). It can also detect contiguous spread downward into the cardia and more distant metastases to the left lobe of the liver.

Endoscopic ultrasound visualises the oesophageal wall as a multilayered structure. The layers represent ultrasound interfaces rather than true anatomical layers, but there is close enough

Figure 62.48 Computed tomography scan demonstrating liver metastases.

Figure 62.49 Endosonography demonstrating an 'early' tumour. Note the preservation of the outer dark wall layer that represents the muscle coat.

Figure 62.50 Endosonography demonstrating an 'advanced' local tumour. Note the breach of the outer white line that represents the interface between the oesophageal wall and the mediastinum.

Figure 62.51 Endosonography demonstrating malignant nodes. These are usually large, hypoechoic and round compared with normal nodes.

correlation to allow accurate assessment of the depth of invasion through the oesophageal wall. Structures smaller than 5 mm can be clearly seen enabling very small nodes to be imaged. The EUS image morphology of such structures provides an additional means of distinguishing malignant from reactive or benign lymph nodes. For submucosal lesions, EUS can demonstrate the wall layer of origin of a lesion, suggesting the likely histological type.

Narrow EUS instruments are available for insertion over a guidewire to minimise the risk of technical failure, and linear array echoendoscopes can be used to biopsy lesions that might signify incurability outside the wall of the gastrointestinal tract (e.g. coeliac lymph nodes).

Positron emission tomography/computed tomography scanning

Positron emission tomography (PET) in the context of cancer staging relies on the generally high metabolic activity (particularly in the glycolytic pathway) of tumours compared with normal tissues. The patient is given a small dose of the radiopharmaceutical agent 18F-fluorodeoxyglucose (FDG). This enters cells and is phosphorylated. FDG-6-phosphate cannot be metabolised further and, because it is a highly polar molecule, it cannot easily diffuse back out of the cell. After intravenous injection of FDG, it continuously accumulates in metabolically active cells. Primary oesophageal cancers are usually sufficiently active to be easily visible, and spatial resolution of positive PET areas occurs down to about 5–8 mm. When used in isolation, there are problems with the anatomical location of these areas. This has been significantly improved by combining PET with CT (Figure 62.52). Although there are wide variations between centres, a change in stage is frequently reported in around 15 per cent of patients. It has also been suggested that a reduction in PET activity following chemotherapy might be a way of predicting 'responders' to this approach.

Treatment of malignant tumours

Principles

At the time of diagnosis, around two-thirds of all patients with oesophageal cancer will already have incurable disease. The aim of palliative treatment is to overcome debilitating or distressing symptoms while maintaining the best quality of life possible for the patient. Some patients do not require specific therapeutic interventions, but do need supportive care and appropriate liaison with community nursing and hospice care services.

As dysphagia is the predominant symptom in advanced

oesophageal cancer, the principal aim of palliation is to restore adequate swallowing. A variety of methods are available and, given the short life expectancy of most patients, it is important that the choice of treatment should be tailored to each individual. Tumour location and endoscopic appearance are important in this regard, as is the general condition of the patient.

Once oesophageal neoplasms reach the submucosal layer of the oesophagus, the tumour has access to the lymphatic system, meaning that, even at this early local stage, there is an incidence of nodal positivity for both squamous cell carcinoma and adenocarcinomas of between 10 and 50 per cent. The principle of oesophagectomy is to deal adequately with the local tumour in order to minimise the risk of local recurrence and achieve an adequate lymphadenectomy to reduce the risk of staging error. Although studies in Japan would indicate that more extensive lymphadenectomy is associated with better survival, this may simply reflect more accurate staging. A number of studies support the view that the proximal extent of resection should ideally be 10 cm above the macroscopic tumour and 5 cm distal. When such a margin cannot be achieved proximally, particularly with squamous cell carcinoma, there is evidence that postoperative radiotherapy can minimise local recurrence, although not improve survival.

Adenocarcinoma commonly involves the gastric cardia and may therefore extend into the fundus or down the lesser curve. Some degree of gastric excision is essential in order to achieve adequate local clearance and accomplish an appropriate lymphadenectomy. Excision of contiguous structures, such as crura, diaphragm and mediastinal pleura, needs to be considered as a method of creating negative resection margins.

The rarity of intramucosal cancer in symptomatic patients means that there are no randomised studies to compare different approaches to this type of very early disease. Even in Barrett's oesophagus, where high-grade dysplasia and early cancer coexist, many centres favour oesophagectomy in fit patients. Endoscopic mucosal resection for these apparently early lesions has become increasingly popular, providing either a cure or at least sufficient histological information upon which to base a further management strategy. Photodynamic therapy (PDT) is an alternative approach that has largely been used in patients who were either unfit or unwilling to undergo surgery. This endoscopic technique relies on the administration of a photosensitiser that is taken up preferentially by dysplastic and malignant cells followed by exposure of an appropriate segment of the oesophagus to laser light. The main drawback is skin photosensitisation, so patients must avoid sunlight exposure in the short term. PDT is also associated with a risk of stricture formation although, as the technique and photosensitising agents improve, these problems are reducing.

Surgery alone is best suited to patients with disease confined to the oesophagus (T1, T2) without nodal metastasis (N0). As a result of careful preoperative investigation, most of these patients are now identifiable and can be offered surgery alone, with a prospect of cure between 50 and 80 per cent. Patients with more advanced stages of disease require either multimodal approaches or entry into appropriate trials.

It is essential that oesophagectomy should be performed with a low hospital mortality and complication rate. Case selection, volume and experience of the surgical team are all important. Preoperative risk analysis has shown that this can play a major part in reducing hospital mortality. There are really no circum-

Figure 62.52 Positron emission tomography/computed tomography demonstrating a primary tumour and a distant metastatic node.

stances in the Western world in which surgery should be undertaken if it is not part of an overall treatment plan aimed at cure (Summary box 62.12).

Summary box 62.12

Treatment of carcinoma of the oesophagus

- Radical oesophagectomy is the most important aspect of curative treatment
- Neoadjuvant treatments before surgery may improve survival in a proportion of patients
- Chemoradiotherapy alone may cure selected patients, particularly those with squamous cell cancers
- Useful palliation may be achieved by chemo/radiotherapy or endoscopic treatments

Treatments with curative intent

Surgery

Histological tumour type, location and the extent of the proposed lymphadenectomy all influence the operative approach. This is largely an issue of surgical preference, although it should be recognised that a left thoracoabdominal approach is limited proximally by the aortic arch and should be avoided when the primary tumour is at or above this level. Similarly, transhiatal oesophagectomy is unsuitable for most patients with squamous cell carcinoma because a complete mediastinal lymphadenectomy is not easily achieved by this approach. The most widely practised approach in the West is the two-phase Ivor Lewis (sometimes called Lewis–Tanner) operation (Figure 62.53), with an initial laparotomy and construction of a gastric tube, followed by a right thoracotomy to excise the tumour and create an oesophagogastric anastomosis. The closer this is placed to the apex of the thoracic cavity, the fewer problems there are

Figure 62.53 The two usual approaches for surgery of the oesophagus are the thoracoabdominal (a), which opens the abdominal and thoracic cavities together, and the two-stage Ivor Lewis approach (b), in which the abdomen is opened first, closed and then the thoracotomy is performed. In the McKeown operation, a third incision in the neck is made to complete the cervical anastomosis.

with reflux disease. Three-phase oesophagectomy (McKeown) may be more appropriate for more proximal tumours in order to achieve better longitudinal clearance, although the additional distance gained is less than many surgeons believe. A third cervical incision also permits lymphadenectomy in this region.

The extent of lymphadenectomy is highly controversial. For squamous cell carcinoma, because a higher proportion of patients will have middle- and upper-third tumours in the thoracic oesophagus, the rationale behind a three-phase operation with three-field lymphadenectomy is more understandable, even though this approach has not been widely adopted in the West. For adenocarcinoma, the incidence of metastases in the neck is relatively low in the context of patients who would otherwise be curable. For this reason, two-phase operations with two-field lymphadenectomy seem the most logical operations. While two-field lymphadenectomy does not substantially increase operative morbidity or mortality, the same cannot be said for more extended operations.

The introduction of minimal access techniques has been pioneered in Australia by Gotley and Smithers and in North America by Luketich. In experienced hands, the open operation can be reproduced without significant compromise. As yet, benefits seem to be confined to reduced wound pain and the absence of specific complications associated with long incisions.

While many centres have reduced hospital mortality to single figures following oesophagectomy, the complication rate remains high. At least one-third of all patients will develop some significant complication after surgery. The most common of these is respiratory, followed by anastomotic leakage, chylothorax and injury to the recurrent laryngeal nerves. The most common late problem is benign anastomotic stricture, which seems to be higher with cervical rather than with intrathoracic anastomoses, although the problem is usually easily dealt with by endoscopic dilatation.

Lesions of the cardia that do not involve the oesophagus to any significant extent may be dealt with by extended total gastrectomy to include the distal oesophagus, or by proximal gastrectomy and distal oesophagectomy (Summary box 62.13).

Summary box 62.13

Oesophagogastric surgery

- Beware of satellite nodules proximal to the primary lesion
- Carefully preserve the blood supply of the stomach, both venous and arterial
- Right thoracic approach gives easy access to the oesophagus

Two-phase oesophagectomy (abdomen and right chest, Ivor Lewis)

Mobilisation of the stomach must be done with care as it is essential to have a tension-free, well-vascularised stomach for transposition. The left gastric, short gastric and left gastroepiploic arteries are all divided. The viability of the transposed stomach mainly depends on the right gastroepiploic and, to a lesser extent, the right gastric vessels. It should be noted that venous drainage is as important as arterial supply, and it is essential to perform an accurate anatomical dissection that preserves the

Ivor Lewis, 1895–1982, surgeon, the North Middlesex Hospital, London, UK, and later at Rhyl, North Wales, UK.

Norman Cecil Tanner, 1906–1982, surgeon, Charing Cross Hospital, London, UK.

Kenneth Charles McKeown, 1912–1995, surgeon, Darlington Memorial Hospital, Darlington, County Durham, UK.

right gastroepiploic vein as well as the artery. The stomach is divided to remove the cardia and the upper part of the lesser curve, including the whole of the left gastric artery and its associated lymph nodes.

The approach to the oesophagus through the right chest is straightforward. A thoracotomy with entry above the fifth rib gives excellent access to the mediastinum and the thoracic inlet. The azygos vein is divided, and the whole of the intrathoracic oesophagus can be mobilised along with the thoracic duct (which is ligated by most surgeons) and the mediastinal lymph nodes. The oesophagus is divided just below the thoracic inlet. As most lesions are in the lower or middle thirds, this usually gives adequate proximal clearance of at least 5 cm. Carcinomas of the upper thoracic oesophagus are almost always incurable at the time of diagnosis, and invasion of the trachea is common. If one of these lesions is resectable, it is essential to use an incision in the neck (McKeown or three-phase operation) and to resect more of the oesophagus than is customary in the operation of subtotal oesophagectomy.

Oesophagogastric anastomosis may be performed equally well by hand or by stapler. Both methods require attention to detail. In experienced hands, clinical anastomotic leakage should be less than 5 per cent. Most surgeons still prefer to keep the patient nil-by-mouth for 5–7 days. Most centres have abandoned the use of routine contrast swallows in patients who are clinically well. Conversely, aggressive investigation of a suspected leak is mandatory for any unexplained fever or clinical event. This may involve contrast radiology, CT scan or endoscopy to resolve the situation adequately.

Postoperative nutritional support remains controversial. There is general agreement that parenteral feeding is associated with more nosocomial infection, including pneumonia, than enteral feeding. It is also expensive. If nutritional support is given, a feeding jejunostomy is probably the best method.

Transhiatal oesophagectomy (without thoracotomy)

This approach was popularised for cancer by Orringer, adapting a technique developed in Brazil by Pinotti for the removal of Chagas's megaesophagus (see below under Achalasia). The stomach is mobilised through a midline abdominal incision, and the cervical oesophagus is mobilised through an incision in the neck. The diaphragm is then opened from the abdomen, and the posterior mediastinum is entered. The lower oesophagus and the tumour are mobilised under direct vision, and the upper oesophagus is mobilised by blunt dissection. This approach can provide an adequate removal of the tumour and lymph nodes in the lower mediastinum, but it is not possible to remove the nodes in the middle or upper mediastinum. It may be a useful procedure for lesions of the lower oesophagus, but is hazardous for a middle-third lesion that may be adherent to the bronchus or to the azygos vein.

Neoadjuvant treatments with surgery

Apart from the earliest stages of disease, surgery alone produces relatively few cures in either squamous cell carcinoma or adenocarcinoma patients. This led to a number of trials throughout the 1980s and 1990s to investigate the value of chemotherapy and surgery or chemoradiotherapy and surgery compared with surgery alone. Some studies relate only to squamous cell cancer, and many are open to criticism on the grounds of trial design or patient numbers. Nevertheless, positive results in favour of neo-

adjuvant therapy for adenocarcinoma in two studies as well as a limited meta-analysis indicate that it is no longer appropriate to consider surgery alone as the 'gold standard' treatment for most patients who are surgical candidates with adenocarcinoma. The exact role of surgery in a multimodal approach to squamous cell carcinoma is an unresolved issue.

Gastro-oesophageal reflux following oesophagogastric resection

Gastro-oesophageal reflux may be a major problem following any operation that involves resecting the cardia. Reflux may present with the typical symptoms of GORD or with a peptic stricture at the site of the anastomosis. However, the presentation may be different with a miserable patient who fails to thrive following the operation and who is then suspected of having recurrent cancer. This atypical presentation is particularly common following total gastrectomy with an inadequate reconstruction that allows bile reflux (Summary box 62.14).

Summary box 62.14

Postoesophagectomy

- Reflux may be a problem following resection
- Symptoms may be atypical
- Reflux may be limited or avoided by subtotal oesophagectomy and gastric transposition high in the chest

Non-surgical treatments

Radiotherapy alone was widely used as a single-modality treatment for squamous cell carcinoma of the oesophagus until the late 1970s. The five-year survival rate overall was 6 per cent. As a result, multimodal approaches were adopted throughout the 1980s, initial trials indicating that similar long-term survival rates could be obtained with surgery. Subsequent randomised studies essentially confined to patients with squamous cell carcinoma have indicated significant survival advantages with chemoradiotherapy over radiotherapy alone. While it is clear that chemoradiotherapy does offer a prospect of cure for patients who may not be fit for surgery, particularly in squamous cell carcinoma, the high rate of locoregional failure has meant that surgery remains the mainstay of attempted curative treatments for both adenocarcinoma and squamous cell carcinoma in patients who have potentially resectable disease and are fit for oesophagectomy. In most Western series, this represents about one-third of patients with adenocarcinoma and a slightly lower percentage of patients with squamous cell carcinoma. There has been no formal comparison of the results of definitive radiotherapy or chemoradiotherapy and surgical resection, and it is therefore impossible to make dogmatic statements about the relative merits of each form of treatment (Summary box 62.15).

Summary box 62.15

Alternative therapeutic approaches

- Chemoradiotherapy may be a useful alternative to surgery, especially in unfit patients

Palliative treatment

Surgical resection and external beam radiotherapy may be used for palliation, but are not suitable when the expected survival is short, as most of the remainder of life will be spent recovering from the 'treatment'. Surgical bypass is likewise too major a procedure for use in a patient with limited life expectancy. A variety of relatively simple methods of palliation are now available that will produce worthwhile relief of dysphagia with minimal disturbance to the patient (Summary box 62.16).

Summary box 62.16

Palliation

- Palliation should be simple and effective

Intubation has been used for many years following the invention of the Souttar tube, which was made of coiled silver wire. A variety of rigid plastic or rubber tubes were developed for placement under endoscopic and/or radiological control. The technology of intubation has now moved on with the development of various types of expanding metal stent (Figure 62.54). These are also inserted under radiographic or endoscopic control. The stent is collapsed during insertion and released when it is in the correct position. Expanding stents produce a wider lumen for swallowing than rigid tubes. More importantly, it is not necessary to dilate the oesophagus to beyond 8 mm to insert the unexpanded stent through the tumour, so there is a lower risk of injury to the oesophagus.

Endoscopic laser treatment may be used to core a channel through the tumour. It is based on thermal tumour destruction. It produces a worthwhile improvement in swallowing, but has the disadvantage that it has to be repeated every few weeks. Lasers may also be used to unblock a stent that has become occluded by tumour overgrowth. **Other endoscopic methods** include bipolar diathermy, argon-beam plasma coagulation and alcohol injection.

Brachytherapy is a method of delivering intraluminal radiation with a short penetration distance (hence the term brachy) to a tumour. An introduction system is inserted through the tumour, and the treatment is then delivered in a single session lasting approximately 20 minutes. The equipment is expensive to purchase, but running costs are low.

While the above methods are suitable for patients with very advanced disease, the elderly and those with significant comorbidities that would make more aggressive strategies inappropriate, an increasing proportion of patients (particularly with

adenocarcinoma) are being treated by platinum-based chemotherapy. In general, this leads to only a modest prolongation of survival but a better quality of life than in those receiving an endoscopic treatment alone.

Malignant tracheo-oesophageal fistula

Malignant tracheo-oesophageal fistula is a sign of incurable disease. Some have advocated surgical bypass and oesophageal exclusion, but this is a major procedure. An expanding metal stent is probably the best treatment.

Post-cricoid carcinoma

Post-cricoid carcinoma is considered in Chapter 48 in neoplasms of the pharynx.

MOTILITY DISORDERS AND DIVERTICULA

Oesophageal motility disorders

A motility disorder can be readily understood when a patient has dysphagia in the absence of a stricture, and a barium-impregnated food bolus is seen to stick in the oesophagus. If this can be correlated with a specific abnormality on oesophageal manometry, accepting that this is the cause of the patient's symptoms may be straightforward. Unfortunately, this is often not the case. Pain, with or without a swallowing problem, is frequently the dominant symptom, and patients often undergo extensive hospital investigation before the oesophagus is considered as a source of symptoms. Symptoms are often intermittent, and the correlation between symptoms and test 'abnormalities' is poor. Much harm may be done by inappropriate enthusiastic surgery for ill-defined conditions. It should also be remembered that oesophageal dysmotility may be only a feature of a general disturbance in gastrointestinal function (Summary box 62.17).

Summary box 62.17

Oesophageal motility disorders

- May be part of a more diffuse gastrointestinal motility problem
- May be associated with GORD

It is convenient to classify oesophageal motility disorders as in Table 62.3.

Functional pain and the oesophagus

Pain that is assumed to arise from dysfunction of the gastrointestinal tract may reflect abnormal motor activity, abnormal perception or a combination of the two. There is evidence that all three exist. Very high-pressure uncoordinated contractions ('spasm') have been shown to correlate with pain. Distension of a balloon in the oesophagus indicates that some patients have a low threshold for the sensation of pain (visceral hypersensitivity), and this itself may reflect local or central neuronal dysfunction. In practice, the difficulty is in understanding the relative contributions of these elements, so that a logical treatment might follow.

Figure 62.54 Expanding metal stents, covered and uncovered.

Table 62.3 Classification of oesophageal motility disorders

Disorders of the pharyngo-oesophageal junction	Neurological – stroke, motor neurone disease, multiple sclerosis, Parkinson's disease Myogenic – myasthenia, muscular dystrophy Pharyngo-oesophageal (Zenker's) diverticulum
Disorders of the body of the oesophagus	Diffuse oesophageal spasm Nutcracker oesophagus Autoimmune disorders – especially systemic sclerosis (CREST) Reflux associated Idiopathic Allergic Eosinophilic oesophagitis Non-specific oesophageal dysmotility
Disorders of the lower oesophageal sphincter	Achalasia Incompetent lower sphincter (i.e. GORD)

CREST, calcinosis, Raynaud's syndrome, (a)esophageal motility disorders, sclerodactyly and telangiectasia; GORD, gastro-oesophageal reflux disease.

Achalasia

Pathology and aetiology

Achalasia (Greek 'failure to relax') is uncommon, but merits prominence because it is reasonably understood and responds to treatment. It is due to loss of the ganglion cells in the myenteric (Auerbach's) plexus, the cause of which is unknown. In South America, chronic infection with the parasite *Trypanosoma cruzi* causes Chagas' disease, which has marked clinical similarities to achalasia. Achalasia differs from Hirschsprung's disease of the colon because the dilated oesophagus usually contains few ganglion cells, whereas the dilated colon contains normal ganglion cells proximal to a constricted, aganglionic segment. Histology of muscle specimens generally shows a reduction in the number of ganglion cells (and mainly inhibitory neurones) with a variable degree of chronic inflammation. In so-called 'vigorous achalasia', which may be an early stage of the disease, there is inflammation and neural fibrosis, but normal numbers of ganglion cells (Summary box 62.18).

The classic physiological abnormalities are a non-relaxing LOS and absent peristalsis in the body of the oesophagus. While most patients have almost no recognisable contractions, 'vigorous' achalasia has been recognised for many years as a condition where, in its earliest stages, the oesophagus is of normal calibre and still exhibits contractile (although non-peristaltic) activity. In some patients, these uncoordinated contractions result in pain as much as a sense of food sticking. High-resolution

Harald Hirschsprung, 1831–1916, physician, the Queen Louise Hospital for Children, and Professor of Paediatrics, Copenhagen, Denmark, described congenital megacolon in 1888.

Summary box 62.18

Achalasia

- Is uncommon
- Is due to selective loss of inhibitory neurones in the lower oesophagus
- The causes dysphagia and carcinoma must be excluded
- Treatment is by either endoscopic dilatation or surgical myotomy

manometry indicates that there are a number of contraction patterns and these may be important in predicting the outcome of treatment. With time, the oesophagus dilates and contractions disappear, so that the oesophagus empties mainly by the hydrostatic pressure of its contents. This is nearly always incomplete, leaving residual food and fluid. The gas bubble in the stomach is frequently absent, as no bolus with its accompanying normal gas passes through the sphincter. The 'megaesophagus' becomes tortuous with a persistent retention oesophagitis due to fermentation of food residues (Figure 62.55), and this may account for the increased incidence of carcinoma of the oesophagus (Summary box 62.19).

Summary box 62.19

Lower oesophageal stricture

- Beware pseudoachalasia; look for tumour

Pseudoachalasia is an achalasia-like disorder that is usually produced by adenocarcinoma of the cardia (Figure 62.56), but has also been described in relation to benign tumours at this level. It has been presumed that the inability of the sphincter to relax is linked to the loss of body peristalsis, but other cancers outside the oesophagus (bronchus, pancreas) have also been associated with pseudoachalasia.

Clinical features

The disease is most common in middle life, but can occur at any age. It typically presents with dysphagia, although pain (often mistaken for reflux) is common in the early stages. Patients often present late and, having had relatively mild symptoms, remain untreated for many years. Regurgitation is frequent, and there may be overspill into the trachea, especially at night.

Diagnosis

Achalasia may be suspected at endoscopy by finding a tight cardia and food residue in the oesophagus. Barium radiology may show hold-up in the distal oesophagus, abnormal contractions in the oesophageal body and a tapering stricture in the distal oesophagus, often described as a 'bird's beak' (see Figure 62.55). The gastric gas bubble is usually absent. These typical features of well-developed achalasia are often absent, and endoscopy and radiology can be normal. A firm diagnosis is established by oesophageal manometry. Classically, the LOS does not relax completely on swallowing, there is no peristalsis and there is a raised resting pressure in the oesophagus (Figure 62.57). The LOS pressure may be elevated, but is often normal.

Figure 62.55 Achalasia of the oesophagus. (a) Barium swallow showing the smooth outline of the stricture, which narrows to a point at its lower end. (b) Tortuosity and sigmoid appearance of the lower oesophagus. (c) Mediastinal shadow due to a large, fluid-filled oesophagus.

Treatment

Alone among motility disorders, achalasia responds well to treatment. The two main methods are forceful dilatation of the cardia and Heller's myotomy. Comparative studies suggest equivalence in terms of safety, effectiveness and cost when considered over a number of years.

Pneumatic dilatation

This involves stretching the cardia with a balloon to disrupt the muscle and render it less competent. The treatment was first described by Plummer. Many varieties of balloon have been used but, nowadays, plastic balloons with a precisely controlled external diameter are used. If the pressure in the balloon is too high, the balloon is designed to split along its length rather than expanding further. Balloons of 30–40 mm in diameter are available and are inserted over a guidewire (Figure 62.58). Perforation is the major complication. With a 30-mm balloon, the incidence of perforation should be less than 0.5 per cent. The risk of perforation increases with bigger balloons, and they should be used cautiously for progressive dilatation over a period of weeks. Forceful dilatation is curative in 75–85 per cent of cases. The results are best in patients aged more than 45 years (Summary box 62.20).

Ernst Heller, 1877–1964, surgeon, St George's Krankenhaus, Leipzig, Germany, described his operation in 1914 when he performed a double myotomy. In 1923, JH Zaaijer from Leiden in The Netherlands reported that a single anterior myotomy is as good which is performed today.

Henry Stanley Plummer, 1874–1937, physician, the Mayo Clinic, Rochester, MN, USA.

Figure 62.56 Almost achalasia, but note the irregularity of the taper, which indicates carcinoma of the cardia.

Figure 62.57 Manometry in achalasia, showing simultaneous contractions in the body of the oesophagus and incomplete relaxation of the lower oesophageal sphincter (LOS) in response to swallowing.

Figure 62.58 Balloon dilator for the treatment of achalasia by forceful dilatation.

Summary box 62.20

Achalasia

- Beware perforation due to dilatation of achalasia
- Beware postoperative reflux

Heller's myotomy

This involves cutting the muscle of the lower oesophagus and cardia (Figure 62.59). The major complication is gastro-oesophageal reflux, and most surgeons therefore add a partial anterior fundoplication (Heller-Dor's operation). The procedure is ideally suited to a minimal access laparoscopic approach, and most surgeons use intraoperative endoscopy to judge the extent of the myotomy and to ensure that the narrow segment is abolished.

It is successful in more than 90 per cent of cases and may be used after failed dilatation.

Botulinum toxin

This is done by endoscopic injection into the LOS. It acts by interfering with cholinergic excitatory neural activity at the LOS. The effect is not permanent, and the injection usually

Figure 62.59 Heller's myotomy. The incision should not go too far on to the stomach. The lateral extent must enable the mucosa to pout out, to prevent the edges healing together.

has to be repeated after a few months. For this reason, its use is restricted to elderly patients with other comorbidities.

Drugs

Drugs such as calcium channel antagonists have been used but are ineffective for long-term use. However, sublingual nifedipine may be useful for transient relief of symptoms if definitive treatment is postponed.

Other oesophageal motility disorders

Disorders of the pharyngo-oesophageal junction

With the exception of Zenker's diverticulum (see below), most patients with oropharyngeal dysphagia have generalised neurological or muscular disorders with pharyngeal involvement. A small number of patients who have sustained a cerebrovascular accident benefit from myotomy of the cricopharyngeus to alleviate pooling of saliva and nocturnal aspiration, but they should have good deglutition and phonation before this is performed. The operation is also effective in patients with oculopharyngeal muscular dystrophy.

Disorders of the body of the oesophagus

Diffuse oesophageal spasm and nutcracker oesophagus

Diffuse oesophageal spasm is a condition in which there are incoordinate contractions of the oesophagus, causing dysphagia and/or chest pain. The condition may be dramatic, with spastic pressures on manometry of 400–500 mmHg, marked hypertrophy of the circular muscle and a corkscrew oesophagus on barium swallow (Figure 62.60). These abnormal contractions are more common in the distal two-thirds of the oesophageal body, and this may have some relevance to treatment. Making the diagnosis when chest pain is the only symptom may be difficult. Prolonged ambulatory oesophageal manometry that correlates episodes of chest pain with manometric abnormalities may establish the diagnosis.

There is no proven pharmacological or endoscopic treatment. Calcium channel antagonists, vasodilators and endoscopic

dilatation have only transient effects. While the severity and frequency of symptoms may be tolerated by most patients, sometimes the combination of chest pain and dysphagia is sufficiently severe that malnutrition begins. In these patients, extended oesophageal myotomy up to the aortic arch may be required. Surgical treatment of diffuse spasm is more successful in improving dysphagia than chest pain, and caution should be exercised in patients in whom chest pain is the only symptom.

Nutcracker oesophagus is a condition in which peristaltic pressures of more than 180 mmHg develop. It is said to cause chest pain, but there is still some debate as to whether it is a real disorder.

Oesophageal involvement in autoimmune disease

Oesophageal involvement is mainly seen in systemic sclerosis, but may be a feature of polymyositis, dermatomyositis, systemic lupus erythematosus, polyarteritis nodosa or rheumatoid disease. While most involve weak peristalsis, swallowing difficulties may be compounded by pharyngeal problems in the disorders that primarily affect skeletal muscle (e.g. polymyositis) or extraoesophageal problems such as involvement of the cricoarytenoid joint in rheumatoid disease or dry mouth in Sjögren's syndrome. In systemic sclerosis, smooth muscle atrophy causes hypoperistalsis (Figure 62.61). The LOS is involved, leading to a loss of the antireflux barrier. A wide range of symptoms can follow from mild to severe dysphagia accompanied by regurgitation and aspiration. Reflux can be severe and is exacerbated by weak acid clearance so that strictures can occur. There are no drugs that specifically correct the motor disorder, and medical treatment is mainly directed at minimising reflux-induced damage with PPIs. A small number of patients may require antireflux surgery.

Eosinophilic oesophagitis is a disorder that occurs in children and adults either alone or as a manifestation of eosinophilic gastroenteritis. It is characterised by eosinophilic infiltration of the oesophageal wall, presumably of allergic or idiopathic origin. The most common presenting symptom is dysphagia,

Figure 62.60 Corkscrew oesophagus in diffuse oesophageal spasm.

Figure 62.61 Advanced scleroderma of the oesophagus. The oesophagus dilates, and the lower oesophageal sphincter is widely incompetent.

and more than half have some history of atopy. The oesophagus often seems narrow and friable on endoscopy and may include mucosal rings. The most important feature is the development of deep ulcers leading to stricture development, especially in the proximal oesophagus. The diagnosis is established by endoscopic biopsy.

Elimination diets, topical and systemic steroids all seem to be helpful in the short term, but there is scant information on the long-term impact of any particular approach. Immunotherapy directed against interleukin (IL)-5, which has a major role in eosinophil recruitment, seems to be a promising innovative approach. Although endoscopic dilatation has been recommended, this can create deep ulcers and further scarring, so should be used with caution and only when the above therapies fail.

Pharyngeal and oesophageal diverticula

Most oesophageal diverticula are **pulsion** diverticula that develop at a site of weakness as a result of chronic pressure against an obstruction. Symptoms are mostly caused by the underlying disorder unless the diverticulum is particularly large. **Traction** diverticula (Figure 62.62) are much less common. They are mostly a consequence of chronic granulomatous disease affecting the tracheobronchial lymph nodes due to tuberculosis, atypical mycobacteria or histoplasmosis. Fibrotic healing of the lymph nodes exerts traction on the oesophageal wall and produces a focal outpouching that is usually small and has a conical shape. There may be associated broncholithiasis, and

Figure 62.62 Mid-oesophageal traction diverticulum with the mouth facing downwards.

Figure 62.63 Mid-oesophageal diverticulum with a tracheo-oesophageal fistula.

additional complications may occur, such as aerodigestive fistulation (Figure 62.63) and bleeding.

Zenker's diverticulum (pharyngeal pouch) is not really an oesophageal diverticulum as it protrudes posteriorly above the cricopharyngeal sphincter through the natural weak point (the dehiscence of Killian) between the oblique and horizontal (cricopharyngeus) fibres of the inferior pharyngeal constrictor (Figures 62.64 and 62.65). The exact mechanism that leads to its formation is unknown, but it involves loss of the coordination between pharyngeal contraction and opening of the upper sphincter. When the diverticulum is small, symptoms largely reflect this incoordination with predominantly pharyngeal dysphagia. As the pouch enlarges, it tends to fill with food on eating, and the fundus descends into the mediastinum. This leads to halitosis and oesophageal dysphagia. Treatment can be undertaken endoscopically with a linear cutting stapler to divide the septum between the diverticulum and the upper oesophagus, producing a diverticulo-oesophagostomy, or can be done by open surgery involving pouch excision, pouch suspension (diverticulectomy) and/or myotomy of the cricopharyngeus. All techniques have good results.

Mid-oesophageal diverticula are usually small pulsion diverticula of no particular consequence. The underlying motility disorder does not usually require treatment. Some pulsion diverticula may fistulate into the trachea (Figure 62.63), but this is more common with traction diverticula in granulomatous disease.

Figure 62.64 The typical appearances of: (a) a small pharyngeal pouch with a prominent cricopharyngeal impression and 'streaming' of barium, indicating partial obstruction; and (b) a large pouch extending behind the oesophagus towards the thoracic inlet.

Epiphrenic diverticula are pulsion diverticula situated in the lower oesophagus above the diaphragm (Figure 62.66). They may be quite large, but cause surprisingly few symptoms. They again probably reflect some loss of coordination between an

Figure 62.65 The endoscopic appearance of the mouth of a pharyngeal pouch posterior to the normal opening (left) of the oesophagus.

incoming pressure wave and appropriate relaxation of the LOS. This needs to be acknowledged in the surgical management of the patient. The diverticulum, in isolation, should not be assumed to account for a patient's illness just because it looks dramatic on a radiograph. Large diverticula may be excised, and this should be combined with a myotomy from the site of the diverticulum down to the cardia to relieve functional obstruction (Summary box 62.21).

Summary box 62.21

Oesophageal diverticula

- Diverticula are indicators of a motor disorder and not necessarily the cause of symptoms

Diffuse intramural pseudodiverticulosis is a rare condition in which there are multiple tiny outpouchings from the lumen of the oesophagus. The pseudodiverticula are dilated excretory ducts of oesophageal sebaceous glands. It is questionable whether the condition produces any symptoms in its own right.

OTHER NON-NEOPLASTIC CONDITIONS

Schatzki's ring

Schatzki's ring is a circular ring in the distal oesophagus (Figure 62.67), usually at the squamocolumnar junction. The cause is obscure, but there is a strong association with reflux disease. The core of the ring consists of variable amounts of fibrous tissue and cellular infiltrate. Most rings are incidental findings. Some are associated with dysphagia and respond to dilatation in conjunction with medical antireflux therapy.

Richard Schatzki, 1901–1992, American radiologist, a German by birth and medical training, he became Chief of Radiology Department, Mount Auburn Hospital, Cambridge, MA, USA.

Figure 62.66 Epiphrenic diverticulum proximal to the gastro-oesophageal sphincter. (a) Small and asymptomatic; (b) large, symptomatic and appearing as a gas-filled bubble on the chest radiograph.

Figure 62.67 Schatzki's ring, a thin submucosal web completely encircling the whole of the lumen, usually situated at the squamocolumnar junction.

Oesophageal infections

Bacterial infection of the oesophagus is rare, but fungal and viral infections do occur. They are particularly important in immunocompromised patients.

Oesophagitis due to *Candida albicans* is relatively common in patients taking steroids (especially transplant patients) or those undergoing cancer chemotherapy. It may present with dysphagia or odynophagia. There may be visible thrush in the throat. Endoscopy shows numerous white plaques that cannot be moved, unlike food residues (Figure 62.68). Biopsies are diagnostic. In severe cases, a barium swallow may show dramatic mucosal ulceration and irregularity that is surprisingly similar to the appearance of oesophageal varices (Figures 62.69 and 62.70). Treatment is with a topical antifungal agent.

Dysphagia and odynophagia can also be caused by herpes simplex virus and cytomegalovirus (CMV). With the former, there may be a history of a herpetic lesion on the lip some days earlier, and endoscopy may reveal vesicles or small ulcers with raised margins, usually in the upper half of the oesophagus. CMV infection may be apparent in graft-versus-host disease following bone marrow transplantation. It has a characteristic endoscopic appearance with a geographical, serpiginous border. In both cases, endoscopic biopsy is diagnostic.

Chagas' disease

This condition is confined to South American countries, but is of interest because oesophageal symptoms occur that are similar

Figure 62.68 Endoscopic appearance of oesophageal candidiasis.

Figure 62.69 Oesophageal candidiasis with shaggy appearance of mucosal defects.

to severe achalasia. It is caused by a protozoan, *Trypanosoma cruzi*, transmitted by an insect vector. Parasites reach the bloodstream and, after a long latent period, there is damage particularly to cardiac and smooth muscle. Destruction of both Auerbach's and Meissner's plexuses leads to acquired megaesophagus.

Figure 62.70 Oesophageal varices with smooth outline of the filling defects.

Crohn's disease

The oesophagus is not commonly affected by symptomatic Crohn's disease. However, pathological studies indicate that it may be present in 20 per cent of patients without symptoms. Symptoms are often severe, and a diagnosis of reflux oesophagitis is usually made on the basis of retrosternal pain and dysphagia. Endoscopy shows extensive oesophagitis that extends much further proximally than reflux oesophagitis. Biopsies may be diagnostic, but may show only non-specific inflammation. In severe cases, deep sinuses occur, and fistulation has been described. Crohn's oesophagitis is said to respond poorly to medical treatment and, although balloon dilatation of strictures and surgical resection for multiple internal fistulae have both been described, these interventions should be used with great caution.

Plummer-Vinson syndrome

This is also called the Paterson-Kelly syndrome or **sideropenic dysphagia**. The original descriptions are vague and poorly supported by evidence of a coherent syndrome. Dysphagia is said to occur because of the presence of a postcricoid web that is associated with iron deficiency anaemia, glossitis and koilonychia. The classical syndrome is rarely complete. Some patients may have oropharyngeal leukoplakia, and this may account for an alleged increased risk of developing hypopharyngeal cancer.

Porter Paisley Vinson, 1890–1959, physician, the Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.
 Adam Brown Kelly, 1865–1941, surgeon, the Ear, Nose and Throat Department, the Royal Victoria Infirmary, Glasgow, UK.
 Donald Rose Paterson, 1863–1939, surgeon, the Ear, Nose and Throat Department, the Royal Infirmary, Cardiff, Wales, UK.
 Vinson, Kelly and Paterson, all described this syndrome independently in 1919.

Webs certainly occur in the upper and middle oesophagus, usually without any kind of associated syndrome. They are nearly always thin diaphanous membranes identified coincidentally by contrast radiology. Even symptomatic webs that cause a degree of obstruction may be inadvertently ruptured at endoscopy. Few require formal endoscopic dilatation.

Vascular abnormalities affecting the oesophagus

Several congenital vascular anomalies may produce dysphagia by compression of the oesophagus. Classically, this results from an aberrant right subclavian artery (*arteria lusoria*). However, the oesophagus is more commonly compressed by vascular rings, such as a double aortic arch. Dysphagia occurs in only a minority of cases and usually presents early in childhood, although it can occur in the late teens. Treatment is usually by division of the non-dominant component of the ring.

In adults, acquired causes include aneurysm of the aorta, diffuse cardiac enlargement and pressure from the left common carotid or vertebral arteries. It is rare that symptom severity justifies surgical intervention.

Mediastinal fibrosis

This rare condition can occur alone or in conjunction with retroperitoneal fibrosis. The cause is unknown and, while the major consequences are usually cardiovascular as a result of caval compression, dysphagia can occur. The existence of irreparable cardiovascular problems usually precludes surgical intervention on the oesophagus.

CHAPTER 63

Stomach and duodenum

LEARNING OBJECTIVES

- To understand the gross and microscopic anatomy and pathophysiology of the stomach in relation to disease
- To be able to decide on the most appropriate techniques to use in the investigation of patients with complaints relating to the stomach and duodenum
- To understand the critical importance of gastritis and *Helicobacter pylori* in upper gastrointestinal disease
- To be able to investigate and treat peptic ulcer disease and its complications
- To be able to recognise the presentation of gastric cancer and understand the principles involved in its treatment
- To know about the causes of duodenal obstruction and the presentation of duodenal tumours

INTRODUCTION

The function of the stomach is to act as a reservoir for ingested food. It also serves to break down foodstuffs mechanically and commence the processes of digestion before these products are passed on into the duodenum.

GROSS ANATOMY OF THE STOMACH AND DUODENUM

Blood supply

Arteries

The stomach has an arterial supply on both lesser and greater curves (Figure 63.1). On the lesser curve, the left gastric artery, a branch of the coeliac axis, forms an anastomotic arcade with the right gastric artery, which arises from the common hepatic artery. Branches of the left gastric artery pass up towards the cardia. The gastroduodenal artery, which is also a branch of the hepatic artery, passes behind the first part of the duodenum, highly relevant with respect to the bleeding duodenal ulcer. Here it divides into the superior pancreaticoduodenal artery and the right gastroepiploic artery. The superior pancreaticoduodenal artery supplies the duodenum and pancreatic head, and forms an anastomosis with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The right gastroepiploic artery runs along the greater curvature of the stomach, eventually forming an anastomosis with the left gastroepiploic artery, a branch of the splenic artery. This vascular arcade, important for the construction of the gastric conduit in oesophageal resection, is often variably incomplete. The fundus

of the stomach is supplied by the vasa brevia (or short gastric arteries), which arise from near the termination of the splenic artery.

Veins

In general, the veins are equivalent to the arteries, those along the lesser curve ending in the portal vein and those on the greater curve joining via the splenic vein. On the lesser curve, the coronary vein is particularly important. It runs up the lesser

Figure 63.1 The arterial blood supply of the stomach.

curve towards the oesophagus and then passes left to right to join the portal vein. This vein becomes markedly dilated in portal hypertension.

Lymphatics

The lymphatics of the stomach are of considerable importance in the surgery of gastric cancer and are therefore described in detail in the section Spread of carcinoma of the stomach.

Nerves

As with the entire gastrointestinal tract, the stomach and duodenum possess both intrinsic and extrinsic nerve supplies. The intrinsic nerves exist principally in two plexuses, the myenteric plexus of Auerbach and the submucosal plexus of Meissner. Compared with the rest of the gut, the submucosal plexus of the stomach contains relatively few ganglionic cells, as does the myenteric plexus in the fundus. However, in the antrum the ganglia of the myenteric plexus are well developed. The extrinsic supply is derived mainly from the vagus nerves (CN XI), fibres of which originate in the brainstem. The vagal plexus around the oesophagus condenses into bundles that pass through the oesophageal hiatus (Figure 63.2), the posterior bundle being usually identifiable as a large nerve trunk. Vagal fibres are both afferent (sensory) and efferent. The efferent fibres are involved in the receptive relaxation of the stomach and the stimulation of gastric motility, as well as having the well-known secretory function. The sympathetic supply is derived mainly from the coeliac ganglia.

MICROSCOPIC ANATOMY OF THE STOMACH AND DUODENUM

The gastric epithelial cells are mucus producing and are turned over rapidly. In the pyloric part of the stomach, and also the duodenum, mucus-secreting glands are found. Most of the specialised cells of the stomach (parietal and chief cells) are found in the gastric crypts (Figure 63.3). The stomach also has numerous endocrine cells.

Parietal cells

These are in the body (acid-secreting portion) of the stomach and line the gastric crypts, being more abundant distally. They are responsible for the production of hydrogen ions to form hydrochloric acid. The hydrogen ions are actively secreted by the proton pump, a hydrogen–potassium-ATPase (Sachs), which exchanges intraluminal potassium for hydrogen ions. The potassium ions enter the lumen of the crypts passively, but the hydrogen ions are pumped against an immense concentration gradient (1 000 000:1).

Chief cells

These lie principally proximally in the gastric crypts and produce pepsinogen. Two forms of pepsinogen are described: pepsinogen I and pepsinogen II. Both are produced by the chief cell, but pepsinogen I is produced only in the stomach. The ratio between pepsinogens I and II in the serum decreases with gastric atrophy. Pepsinogen is activated in the stomach to produce the digestive protease, pepsin.

Endocrine cells

The stomach has numerous endocrine cells, which are critical to its function. In the gastric antrum, the mucosa contains G cells, which produce gastrin. Throughout the body of the stomach, enterochromaffin-like (ECL) cells are abundant and produce histamine, a key factor in driving gastric acid secretion. In addition, there are large numbers of somatostatin-producing D cells throughout the stomach, and somatostatin has a negative regulatory role. The peptides and neuropeptides produced in the stomach are discussed later.

Duodenum

The duodenum is lined by a mucus-secreting columnar epithelium. In addition, Brunner's glands lie beneath the mucosa and are similar to the pyloric glands in the pyloric part of the stomach. Endocrine cells in the duodenum produce cholecystokinin and secretin.

Figure 63.2 The anatomy of the anterior and posterior vagus nerves in relation to the stomach.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wrocław, Poland), described the myenteric plexus in 1862.

George Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucosal plexus in 1852.

George Sachs, Professor of Medicine, CURE, Los Angeles, CA, USA.

Johann Conrad Brunner, 1653–1729, Professor of Anatomy at Heidelberg, Germany and later at Strasbourg, France, described these glands in 1687.

PHYSIOLOGY OF THE STOMACH AND DUODENUM

The stomach mechanically breaks up ingested food and, together with the actions of acid and pepsin, forms chyme that passes into the duodenum. In contrast with the acidic environment of the stomach, the environment of the duodenum is alkaline, due to the secretion of bicarbonate ions from both the pancreas and the duodenum. This neutralises the acid chyme and adjusts the luminal osmolarity to approximately that of plasma. Endocrine cells in the duodenum produce cholecystokinin, which stimulates the pancreas to produce trypsin and the gall bladder to contract. Secretin is also produced by the endocrine cells of the duodenum. This hormone inhibits gastric acid secretion and promotes production of bicarbonate by the pancreas (Summary box 63.1).

Gastric acid secretion

The secretion of gastric acid and pepsin tends to run in parallel, although the understanding of the mechanisms of gastric acid secretion is considerably greater than that of pepsin. Numerous factors are involved to some degree in the production of the

Figure 63.3 The histological appearance of a gastric gland. The mucus-secreting cells are seen at the mucosal surface, the eosinophilic parietal cells superficially in the glands, and the basophilic chief cells in the deepest layer.

Summary box 63.1

The anatomy and physiology of the stomach

- The stomach acts as a reservoir for food and commences the process of digestion
- Gastric acid is produced by a proton pump in the parietal cells, which in turn is controlled by histamine acting on the H_2 -receptors
- The histamine is produced by the endocrine gastric ECL cells in response to a number of factors, particularly gastrin and the vagus
- Proton pump inhibitors abolish gastric acid production, whereas H_2 -receptor antagonists only markedly reduce it
- The gastric mucous layer is essential to the integrity of the gastric mucosa

gastric acid. These include neurotransmitters, neuropeptides and peptide hormones. This complexity need not detract from the fact that there are basic principles that are relatively easily understood (Figure 63.4). Hydrogen ions are produced by the parietal cell by the proton pump. Although numerous factors can act on the parietal cell, the most important of these is histamine, which acts via the H_2 -receptor. Histamine is produced, in turn, by the ECL cells of the stomach and acts in a paracrine (local) fashion on the parietal cells. These relationships explain why proton pump inhibitors can abolish gastric acid secretion, as they act on the final common pathway – hydrogen ion secretion. H_2 -receptor antagonists have profound effects on gastric acid secretion, but this is not insurmountable (Figure 63.4). The ECL cell produces histamine in response to a number of stimuli that include the vagus nerve and gastrin. Gastrin is released by the G cells in response to the presence of the food in the stomach. The production of gastrin is inhibited by acid, hence creating a negative feedback loop. Various other peptides, including secretin, inhibit gastric acid secretion.

Classically, three phases of gastric secretion are described. The cephalic phase is mediated by vagal activity, secondary

Figure 63.4 The parietal cell in relation to the mechanism of gastric acid secretion. G, gastrin receptor; H, histamine receptor; M, muscarinic receptor.

to sensory arousal as first demonstrated by Pavlov. The gastric phase is a response to food within the stomach, which is mediated principally, but not exclusively, by gastrin. In the intestinal phase, the presence of chyme in the duodenum and small bowel inhibits gastric emptying and, the acidification of the duodenum leads to the production of secretin, which inhibits gastric acid secretion, along with numerous other peptides originating from the gut. The stomach also possesses somatostatin-containing D cells. Somatostatin is released in response to a number of factors including acidification. This peptide acts probably on the G cell, the ECL cell and the parietal cell itself to inhibit the production of acid.

Gastric mucus and the gastric mucosal barrier

The gastric mucous layer is essential to the integrity of the gastric mucosa. It is a viscid layer of mucopolysaccharides produced by the mucus-producing cells of the stomach and the pyloric glands. Gastric mucus is an important physiological barrier to protect the gastric mucosa from mechanical damage, and also the effects of acid and pepsin. Its considerable buffering capacity is enhanced by the presence of bicarbonate ions within the mucus. Many factors can lead to the breakdown of this gastric mucous barrier. These include bile, non-steroidal anti-inflammatory drugs (NSAIDs), alcohol, trauma and shock. Tonometry studies have shown that, of all the gastrointestinal tract, the stomach is the most sensitive to ischaemia following a hypovolaemic insult and also the slowest to recover. This may explain the high incidence of stress ulceration in the stomach.

Peptides and neuropeptides in the stomach and duodenum

As with most of the gastrointestinal tract, the endocrine cells of the stomach produce peptide hormones and neurotransmitters. Previously, nerves and endocrine cells were considered distinct in terms of their products. However, it is increasingly realised that there is enormous overlap within these systems. Many peptides recognised as hormones may also be produced by neurones, hence the term neuropeptides. The term 'messenger' can be used to describe all such products. There are three conventional modes of action that overlap.

- 1 Endocrine.** The messenger is secreted into the circulation, where it affects tissues that may be remote from the site of origin (Bayliss and Starling).
- 2 Paracrine.** Messengers are produced locally and have local effects on tissues. Neurones and endocrine cells both act in this way.
- 3 Neurocrine** (classical neurotransmitter). Messengers are produced by the neurone via the synaptic knob and pass across the synaptic cleft to the target.

Many peptide hormones act on the intrinsic nerve plexus of the gut (see later) and influence motility. Similarly, neuropeptides may influence the structure and function of the mucosa. Some of these peptides, neuropeptides and neurotransmitters are shown in Table 63.1.

Gastroduodenal motor activity

The motility of the entire gastrointestinal tract is modulated to a large degree by its intrinsic nervous system. Critical in this process is the migrating motor complex (MMC). In the fasted

Table 63.1 Function and source of peptides and neuropeptides in the stomach.

Function	Source
Stimulate secretion	
Gastrin	G cells

state, and after food has cleared, in the small bowel there is a period of quiescence lasting in the region of 40 minutes (phase I). There follows a series of waves of electrical and motor activity, also lasting for about 40 minutes, propagated from the fundus of the stomach in a caudal direction at a rate of about 3 per minute (phase II). These pass as far the pylorus, but not beyond. Duodenal slow waves are generated in the duodenum at a rate of about 10 per minute, which carry down the small bowel. The amplitude of these contractions increases to a maximum in phase III, which lasts for about 10 minutes. This 90-minute

cycle of activity is then repeated. From the duodenum, the MMC moves distally at 5–10 cm/min, reaching the terminal ileum after 1.5 hours.

Following a meal, the stomach exhibits receptive relaxation, which lasts for a few seconds. Following this, adaptive relaxation occurs, which allows the proximal stomach to act as a reservoir. Most of the peristaltic activity is found in the distal stomach (the antral mill) and the proximal stomach demonstrates only tonic activity. The pylorus, which is most commonly open, contracts with the peristaltic wave and allows only a few millilitres of chyme through at a time. The antral contraction against the closed sphincter is important in the milling activity of the stomach. Although the duodenum is capable of generating ten waves per minute, after a meal it only contracts after an antral wave reaches the pylorus. The coordination of the motility of the antrum, pylorus and duodenum means that only small quantities of food reach the small bowel at a time. Motility is influenced by numerous factors, including mechanical stimulation and neuronal and endocrine influences (Table 63.1).

INVESTIGATION OF THE STOMACH AND DUODENUM

Flexible endoscopy

Flexible endoscopy is the 'gold standard' investigation of the upper gastrointestinal tract. The original flexible endoscopes were fiberoptic (Hirschowitz), but now most use a solid-state camera mounted at the instrument's tip (Figures 63.5 and 63.6). Other members of the endoscopy team see the image and this is useful when taking biopsies or performing interventional techniques, and also facilitates teaching and training (Summary box 63.2).

Summary box 63.2

The investigation of gastric disorders

- Flexible endoscopy is the most commonly used and sensitive technique for investigating the stomach and duodenum
- Great care needs to be exercised in performing endoscopy to avoid complications and missing important pathology
- Axial imaging, particularly multislice CT, is useful in the staging of gastric cancer, although it may be less sensitive in the detection of liver metastases than other modalities
- CT/PET is useful in staging gastric cancer
- Endoscopic ultrasound is the most sensitive technique in the evaluation of the 'T' stage of gastric cancer and in the assessment of duodenal tumours
- Laparoscopy is very sensitive in detecting peritoneal metastases, and laparoscopic ultrasound provides an accurate evaluation of lymph node and liver metastases

Flexible endoscopy is more sensitive than conventional radiology in the assessment of the majority of gastroduodenal conditions. This is particularly the case for peptic ulceration, gastritis and duodenitis. In upper gastrointestinal bleeding, endoscopy is far superior to any other investigation and offers the possibil-

Basil I Hirschowitz, born 1925 in South Africa, Professor Emeritus of Medicine, Physiology and Biophysics, University of Alabama, Birmingham, AL, USA and given Lifetime Achievement Award as Physician of the Year.

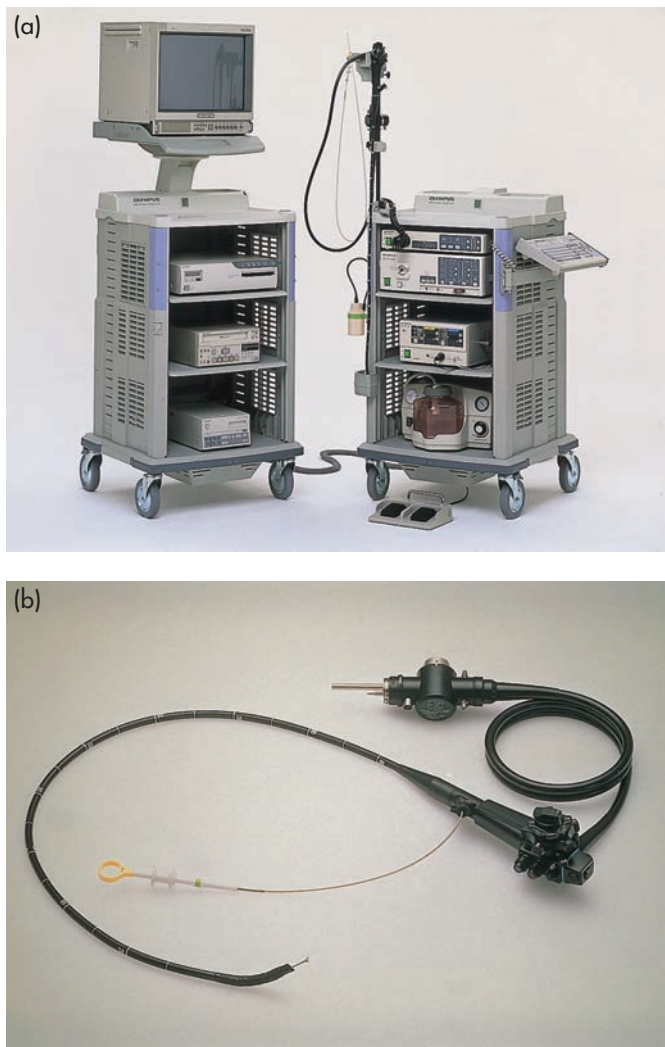

Figure 63.5 A video-gastroscope (courtesy of Keymed (Medical and Industrial Equipment Ltd)). (a) The camera stack. (b) The gastroscoposcope, and biopsy forceps, in the working channel.

ity of endoscopic therapy. In most circumstances it is the only investigation required.

Fiberoptic endoscopy is generally a safe investigation, but it is important that all personnel undertaking these procedures are adequately trained and that resuscitation facilities are always available. Careless and rough handling of the endoscope during intubation of a patient may result in perforations of the pharynx and oesophagus. Any other part of the upper gastrointestinal tract may also be perforated. An inadequately performed endoscopy is also dangerous as a serious condition may be overlooked. This is particularly the case in respect of early and curable gastric cancer, the appearances of which may often be extremely subtle and may be missed by inexperienced endoscopists. A more experienced endoscopist will have a higher index of suspicion for any mucosal abnormalities and will take more biopsies. Spraying the mucosa with dye endoscopically may allow better discrimination between normal and abnormal mucosa, so allowing a small cancer to be more easily seen. In the future, advances in technology may allow 'optical biopsy' to determine the nature of mucosal abnormalities in real time.

Figure 63.6 A view of the normal stomach during endoscopy (courtesy of GNJ Tytgat, Amsterdam, The Netherlands).

Upper gastrointestinal endoscopy can be performed without sedation, but when sedation is required incremental doses of a benzodiazepine are usually administered. Sedation is of particular concern in the case of gastrointestinal bleeding as it may have a more profound effect on the patient's cardiovascular stability. It has now become the standard to use pulse oximetry to monitor patients during upper gastrointestinal endoscopy, and nasal oxygen is often also administered. Buscopan is useful to abolish duodenal motility for examinations of the second and third parts of the duodenum. Examinations of this type are best carried out using a side-viewing endoscope such as is used for endoscopic retrograde cholangiopancreatography (ERCP).

Some patients are relatively resistant to sedation with benzodiazepines, particularly those who are accustomed to drinking alcohol. Increasing the dose of benzodiazepines in these patients may not result in any useful sedation, but merely make the patient more restless and confused. Such patients are sometimes better endoscoped fully awake using a local anaesthetic throat spray and a narrow-gauge endoscope. Whatever the circumstances, it is important that resuscitation facilities are available, including agents that reverse the effects of benzodiazepines, such as flumazenil.

The technology associated with upper gastrointestinal endoscopy is continuing to advance. Instruments which allow both endoscopy and endoluminal ultrasound to be performed simultaneously (see below) are used routinely. Bleeding from the stomach and duodenum can be treated with a number of haemostatic measures. These include injection with various substances, diathermy, heater probes and lasers. These approaches appear to be useful in the treatment of bleeding ulcers, although there are few good controlled trials in this area. There is no good evidence that such interventional procedures at the moment work in patients who are bleeding from very large vessels, such as the gastroduodenal artery or splenic artery, although technology may overcome this problem in the future.

Contrast radiology

Upper gastrointestinal radiology is not used as much as in previous years, as endoscopy is a more sensitive investigation for most gastric problems. Computed tomography (CT) imaging with oral contrast has also replaced contrast radiology in many of the areas where anatomical information is sought, e.g. large hiatus hernias of the rolling type and chronic gastric volvulus. In these conditions it may be difficult for the endoscopist to determine exactly the anatomy or, indeed, negotiate the deformity to see the distal stomach.

Ultrasonography

Standard ultrasound imaging can be used to investigate the stomach, but used conventionally it is less sensitive than other modalities. In contrast, endoluminal ultrasound and laparoscopic ultrasound are probably the most sensitive techniques available in the preoperative staging of gastric cancer. In endoluminal ultrasound, the transducer is usually attached to the distal tip of the instrument. However, devices have been developed which may be passed down the biopsy channel, albeit with poorer image quality. Five layers (Figure 63.7) of the gastric wall may be identified on endoluminal ultrasound and the depth of invasion of a tumour can be assessed with exquisite accuracy (90 per cent accuracy for the 'T' component of the staging). Enlarged lymph nodes can also be identified and the technique's accuracy in this situation is about 80 per cent. Finally, it may be possible to identify liver metastases not seen on axial imaging. Laparoscopic ultrasound is also a very sensitive imaging modality to a large measure because of the laparoscopy itself (see below). It is one of the most sensitive methods of detecting liver metastases from gastric cancer.

An additional use of ultrasound is in the assessment of gastric emptying. Swallowed contrast is utilised, which is designed to be easily seen using an ultrasound transducer. The emptying of this contrast is then followed directly. The accuracy of the technique is similar to that of radioisotope gastric emptying studies (see below).

CT scanning and magnetic resonance imaging

The resolution of CT scanners is continuing to improve, and multislice CT is of increasing value in the investigation of the stomach, especially gastric malignancies (Figure 63.8). The presence of gastric wall thickening associated with a carcinoma

Figure 63.7 Endoscopic ultrasound of the stomach. Five layers can be identified in the normal stomach. A gastric cancer is shown invading the muscle of the gastric wall (courtesy of KeyMed (Medical and Industrial Equipment Ltd)).

Figure 63.8 A computed tomography scan of the abdomen, showing a gastric cancer arising in the body of the stomach.

of any reasonable size can be easily detected by CT, but the investigation lacks sensitivity in detecting smaller and curable lesions. It is much less accurate in 'T' staging than endoluminal ultrasound. Lymph node enlargement can be detected and, based on the size and shape of the nodes, it is possible to be reasonably accurate in detecting nodal involvement with tumour. However, as with all imaging techniques, it is limited. Microscopic tumour deposits in lymph nodes cannot be detected when the node is not enlarged and, in contrast, lymph nodes may undergo reactive enlargement but not contain tumour. These problems apply to all imaging techniques.

The detection of small liver metastases is improving, although in general terms metastases from gastric cancer are less easy to detect using CT than those, for instance, from colorectal cancer. This is because metastases from gastric cancer may be of the same density as liver and may not handle the intravenous contrast any differently. At present, magnetic resonance imaging (MRI) scanning does not offer any specific advantage in assessing the

stomach, although it has a higher sensitivity for the detection of gastric cancer liver metastases than conventional CT imaging.

CT/positron emission tomography

Positron emission tomography (PET) is a functional imaging technique which relies on the uptake of a tracer in most cases by metabolically active tumour tissue. Fluorodeoxyglucose (FDG) is the most commonly used tracer. This tracer has a short half-life hence manufacture and use have to be carefully coordinated. To be of value, anatomical and functional informations need to be linked hence PET/CT is now used universally. It is increasingly being used in the preoperative staging of gastro-oesophageal cancer as it will demonstrate occult spread which renders the patient surgically incurable in up to 10 per cent of patients who would otherwise have undergone major resections (Figure 63.9). PET/CT may also be used to determine the response to neoadjuvant chemotherapy in oesophagogastric malignancies although this is the subject of ongoing studies.

Laparoscopy

This technique is now well used in the assessment of patients with gastric cancer. Its particular value is in the detection of peritoneal disease, which is difficult by any other technique, unless the patient has ascites or bulky intraperitoneal disease. Its main limitation is in the evaluation of posterior extension but other techniques are available to evaluate posterior invasion, especially CT and endoluminal ultrasound. Usually laparoscopy is combined with peritoneal cytology unless laparotomy follows immediately.

Gastric emptying studies

These are useful in the study of gastric dysmotility problems, particularly those that follow gastric surgery. The principle of the examination is that a radioisotope-labelled liquid and solid meal are ingested by the patient and the emptying of the stomach is followed on a gamma camera. This allows the proportion of activity in the remaining stomach to be assessed numerically, and it is possible to follow liquid and solid gastric emptying independently (Figure 63.10).

Figure 63.9 Computed tomography/positron emission tomography of a patient with gastric cancer. The middle pair of images shows the primary tumour. The two images on the left show unsuspected liver metastases, whereas the two on the right show a left cervical node positive for metastases.

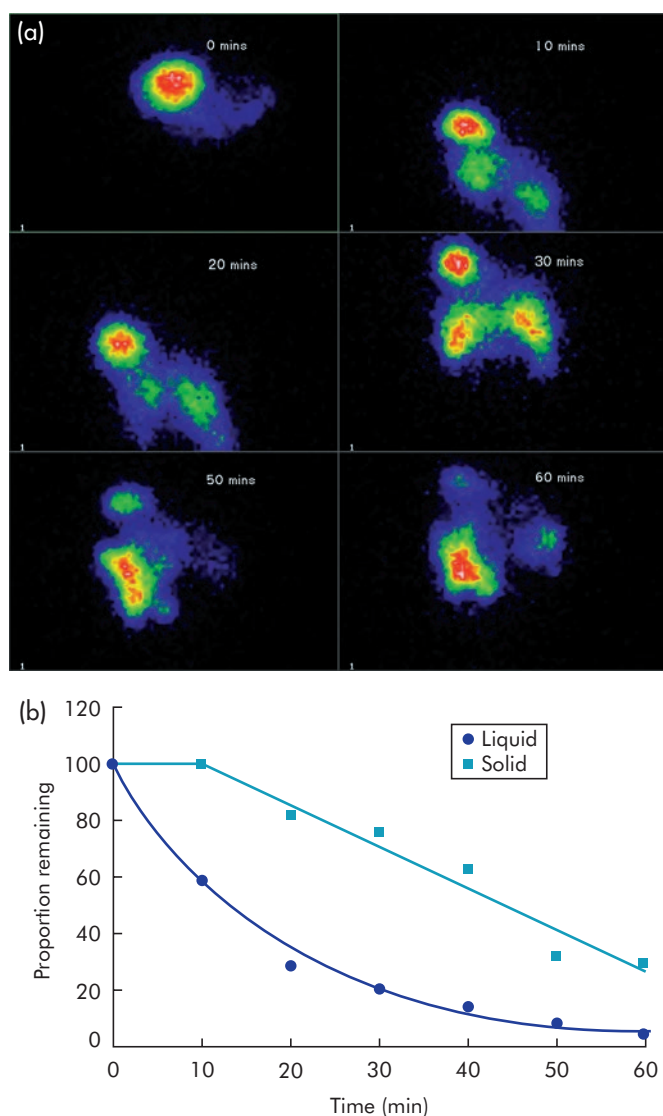

Figure 63.10 Dual-phase solid and liquid gastric emptying. The use of two isotopic labels allows the liquid and solid phases of the emptying to be followed separately. (a) Image acquisition. (b) Gastric emptying curves in a normal individual showing typical lag period in solid phase before linear emptying (courtesy of Dr V Lewington, Southampton, UK).

Angiography

Angiography is used most commonly in the investigation of upper gastrointestinal bleeding that is not identified using endoscopy. Therapeutic embolisation may also be of value in the treatment of bleeding in patients in whom surgery is difficult or inadvisable.

HELICOBACTER PYLORI

Over the last 30 years, this organism has proved to be of overwhelming importance in the aetiology of a number of common gastroduodenal diseases such as chronic gastritis, peptic ulceration and gastric cancer. The organism had unquestionably been observed by a number of workers since Bircher's first description in 1874, but it was not until 1980 that Warren and Marshall,

with enthusiasm but perhaps a lack of caution, ingested the organism to confirm that Koch's postulates could be fulfilled with respect to the gastritis that they succeeded in causing in themselves. Eradication therapy was then employed with mixed success, but both received the Nobel Prize for Medicine and Physiology in 2005. The organism is spiral shaped and is fastidious in its requirements, being difficult to culture outside the mucous layer of the stomach.

One of the characteristics of the organism is its ability to hydrolyse urea, resulting in the production of ammonia, a strong alkali. The effect of ammonia on the antral G cells is to cause the release of gastrin via the previously described negative-feedback loop. This is probably responsible for the modest, but inappropriate, hypergastrinaemia in patients with peptic ulcer disease, which, in turn, may result in gastric acid hypersecretion. The organism's obligate urease activity is utilised by various tests used to detect the presence of the organism, including the ^{13}C and ^{14}C breath tests and the CLO test (a commercially available urease test kit), which is performed on gastric biopsies. The organism can also be detected histologically (Figure 63.11), using the Giemsa or the Ethin–Starey silver stains, and cultured using appropriate media. Previous or current infection with the organism may also be detected serologically. Breath tests or faecal antigen tests are recommended for the pretreatment diagnosis of *H. pylori* infection in the community. Less accurate, hospital-based serology tests have a place within the non-invasive test and treat strategy.

Infection with *H. pylori* leads to the disruption of the gastric mucous barrier by the enzymes produced by the organism, and the inflammation induced in the gastric epithelium is the basis of many of the associated disease processes. The association of

Figure 63.11 Antral mucosa showing colonisation with *Helicobacter pylori* (modified Giemsa stain).

Warren and Marshall were awarded (among many other awards) the Nobel Prize for Physiology or Medicine in 2005 'for their discovery of the bacterium *Helicobacter pylori* and its role in gastritis and peptic ulcer disease'. Marshall ingested the bacteria to prove that *H. pylori* was indeed the causative organism.

Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, started his postulates in 1882. These define the conditions which must be met before an organism can be shown to be the causal agent for a particular disease.

John Robin Warren, born 1937, pathologist, the Royal Perth Hospital, Perth, WA, Australia.

Barry James Marshall, born 1951, physician, the Royal Perth Hospital, Perth, WA, Australia; later became Professor of Medicine at the University of Virginia, VA, USA.

Gustav Giemsa, 1867–1948, a bacteriologist who became Privatdozent in Chemotherapy at the University of Hamburg, Hamburg, Germany.

the organism with chronic (type B) gastritis is not in doubt. Some strains of *H. pylori* produce cytotoxins, notably the *Cag A* and *Vac A* products, and the production of cytotoxins seem to be associated with the ability of the organism to cause gastritis, peptic ulceration and cancer. The effect of the organism on the gastric epithelium is to incite a classical inflammatory response that involves the migration and degranulation of acute inflammatory cells, such as neutrophils, and also the accumulation of chronic inflammatory cells, such as macrophages and lymphocytes.

It is evident how *H. pylori* infection results in chronic gastritis and also how this may progress to gastric ulceration, but for a while it remained an enigma as to how the organism could be involved in duodenal ulceration, as the normal duodenum is not colonised. As mentioned above, the production of ammonia does increase the level of circulating gastrin and it has been shown subsequently that eradication of the organism in patients with duodenal ulcer disease will reduce the acid levels to normal. However, the overlap in gastric acid secretion between normal subjects and those with duodenal ulcers is considerable and the modestly increased acid levels in patients with *Helicobacter*-associated antral gastritis are insufficient to explain the aetiology of duodenal ulceration.

The explanation can probably be found in the phenomenon of duodenal gastric metaplasia. Gastric metaplasia is the normal response of the duodenal mucosa to excess acidity. It can be thought of in the same way as any other metaplasia in the gastrointestinal tract: an attempt by the mucosa to resist an injurious stimulus. Although normal duodenal mucosa cannot be infected with *H. pylori*, gastric metaplasia in the duodenum is commonly infected and this infection results in the same inflammatory process that is observed in the gastric mucosa. The result is duodenitis, which is almost certainly the precursor of duodenal ulceration.

Infection with *H. pylori* may be the most common human infection. The incidence of infection within a population increases with age, and in many populations infection rates of 80–90 per cent are not unusual. Up to 50 per cent of the world's population may be infected with *helicobacter*. It appears that most infection is acquired in childhood and the possibility of infection is inversely related to socioeconomic group. The means of spread has not been identified, but the organism can occur in the faeces and faecal–oral spread seems most likely. The organism is not normally found in saliva or dental plaque. There is evidence in different environments and in different population groups that the manifestations of the infection may be different. Predominantly antral gastritis, which is commonly seen in the West, results initially in increased levels of acid production and peptic ulcer disease, whereas gastritis affecting the body, common in the developing world, may lead to hypochlorhydria and gastric neoplasia.

It has been known since 1984 that *Helicobacter* infection is amenable to treatment with antibiotics. The profound hypochlorhydria produced by proton pump inhibitors combined with antibiotics is also effective in eradicating the organism. Commonly used eradication regimes include a proton pump inhibitor and two antibiotics, such as metronidazole and amoxycillin. Very high eradication rates, in the region of 90 per cent, can be achieved with combinations that include the antibiotic clarithromycin, although it may be that in the future antibiotic resistance will become a problem. Reinfection following suc-

cessful eradication appears rare (<0.5 per cent) but incomplete eradication is a more important clinical problem.

At present, eradication therapy is recommended for patients with duodenal ulcer disease, but not for patients with non-ulcer dyspepsia or in asymptomatic patients who are infected. However, recent data show that a proportion of patients with non-ulcer dyspepsia do respond to treatment. *H. pylori* is now classed by the World Health Organisation as a class 1 carcinogen and it may be that further epidemiological studies on the risk of gastric cancer change the current advice on treatment.

GASTRITIS

The understanding of gastritis has increased markedly following elucidation of the role of *H. pylori* in chronic gastritis (Summary box 63.3).

Summary box 63.3

Gastritis

- The spiral bacterium *H. pylori* is critical in the development of type B gastritis, peptic ulceration and gastric cancer
- Infection appears to be acquired mainly in childhood and the infection rate is inversely associated with socioeconomic status
- Eradication, recommended specifically in patients with peptic ulcer disease, can be achieved in up to 90 per cent of patients with a combination of a proton pump inhibitor and antibiotics, and reinfection is uncommon (<0.5 per cent)
- Erosive gastritis is usually related to the use of NSAIDs
- Type A gastritis is an autoimmune process and is associated with the development of pernicious anaemia and gastric cancer

Type A gastritis

This is an autoimmune condition in which there are circulating antibodies to the parietal cell. This results in the atrophy of the parietal cell mass, hence hypochlorhydria and ultimately achlorhydria. As intrinsic factor is also produced by the parietal cell there is malabsorption of vitamin B12, which, if untreated, may result in pernicious anaemia. In type A gastritis, the antrum is not affected and the hypochlorhydria leads to the production of high levels of gastrin from the antral G cells. This results in chronic hypergastrinaemia. This, in turn, results in hypertrophy of the ECL cells in the body of the stomach, which are not affected by the autoimmune damage. Over time it is apparent that microadenomas develop in the ECL cells of the stomach, sometimes becoming identifiable tumour nodules. Very rarely, these tumours can become malignant. Patients with type A gastritis are predisposed to the development of gastric cancer, and screening such patients endoscopically may be appropriate.

Type B gastritis

There are abundant epidemiological data to support the association of this type of gastritis with *H. pylori*. Most commonly, type B gastritis affects the antrum, and it is these patients who are prone to peptic ulcer disease. *Helicobacter*-associated pancreatitis is also a very common manifestation of infection, but

gastritis affecting the corpus alone does not seem to be associated. However, there are some data to suggest that *Helicobacter* may be involved in the initiation of the process. Patients with pangastritis seem to be most prone to the development of gastric cancer.

Intestinal metaplasia is associated with chronic pangastritis with atrophy. Although intestinal metaplasia per se is common, intestinal metaplasia associated with dysplasia has significant malignant potential and, if this condition is identified, endoscopic screening may be appropriate.

Reflux gastritis

This is caused by enterogastric reflux and is particularly common after gastric surgery. Its histological features are distinct from other types of gastritis. Although commonly seen after gastric surgery, it is occasionally found in patients with no previous surgical intervention or who have had a cholecystectomy. Bile chelating or prokinetic agents may be useful in treatment and as a temporising measure to avoid consideration of revisional surgery. Operation for the condition should be reserved for the most severe cases.

Erosive gastritis

This is caused by agents that disturb the gastric mucosal barrier; NSAIDs and alcohol are common causes. The NSAID-induced gastric lesion is associated with inhibition of the cyclo-oxygenase type 1 (COX-1) receptor enzyme, hence reducing the production of cytoprotective prostaglandins in the stomach. Many of the beneficial anti-inflammatory activities of NSAIDs are mediated by COX-2, and the use of specific COX-2 inhibitors reduces the incidence of these side effects. However, taken long term, COX-2 inhibitors are associated with cardiovascular complications in common with many NSAIDs.

Stress gastritis

This is a common sequel of serious illness or injury and is characterised by a reduction in the blood supply to superficial mucosa of the stomach. Although common, this is not usually recognised unless stress ulceration and bleeding supervene, in which case treatment can be extremely difficult. The condition also sometimes follows cardiopulmonary bypass. Prevention of the stress bleeding from the stomach is much easier than treating it, and hence the routine use of H_2 -antagonists with or without barrier agents, such as sucralfate, in patients who are on intensive care. These measures have been shown to reduce the incidence of bleeding from stress ulceration.

Ménétrier's disease

This is an unusual condition characterised by gross hypertrophy of the gastric mucosal folds, mucus production and hypochlorhydria. The condition is premalignant and may present with hypoproteinaemia and anaemia. There is no treatment other than a gastrectomy. The disease seems to be caused by overexpression of transforming growth factor alpha (TGF- α). Like epidermal growth factor (EGF), this peptide also binds to the EGF receptor. The histological features of Ménétrier's disease may be reproduced in transgenic mice overexpressing TGF- α .

Lymphocytic gastritis

This type of gastritis is seen rarely. It is characterised by the infiltration of the gastric mucosa by T cells and is probably

associated with *H. pylori* infection. The pattern of inflammation resembles that seen in coeliac disease or lymphocytic colitis.

Other forms of gastritis

Eosinophilic gastritis appears to have an allergic basis, and is treated with steroids and cromoglycate. Granulomatous gastritis is seen rarely in Crohn's disease and also may be associated with tuberculosis. Acquired immunodeficiency syndrome (AIDS) gastritis is secondary to infection with cryptosporidiosis. Phlegmonous gastritis is a rare bacterial infection of the stomach found in patients with severe intercurrent illness. It is usually an agonal event.

PEPTIC ULCER

Although the name 'peptic' ulcer suggests an association with pepsin, this is essentially unimportant as in the absence of acid, for instance in type A gastritis with atrophy, peptic ulcers do not occur. All peptic ulcers can be healed by using proton pump inhibitors, which can render a patient virtually achlorhydric (Summary box 63.4).

Summary box 63.4

Peptic ulceration

- Most peptic ulcers are caused by *H. pylori* or NSAIDs and changes in epidemiology mirror changes in these principal aetiological factors
- Duodenal ulcers are more common than gastric ulcers, but the symptoms are indistinguishable
- Gastric ulcers may become malignant and an ulcerated gastric cancer may mimic a benign ulcer
- Gastric antisecretory agents and *H. pylori* eradication therapy are the mainstay of treatment, and elective surgery is very rarely performed
- The long-term complications of peptic ulcer surgery may be difficult to treat
- The common complications of peptic ulcers are perforation, bleeding and stenosis
- The treatment of the perforated peptic ulcer is primarily surgical, although some patients may be managed conservatively

Common sites for peptic ulcers are the first part of the duodenum and the lesser curve of the stomach, but they also occur on the stoma following gastric surgery, the oesophagus and even in a Meckel's diverticulum, which contains ectopic gastric epithelium. In general, the ulcer occurs at a junction between different types of epithelia, the ulcer occurring in the epithelium least resistant to acid damage.

In the past, much distinction has been made between acute and chronic peptic ulcers, but this difference can sometimes be difficult to determine clinically. It is probably best to consider that there is a spectrum of disease from the superficial gastric and duodenal ulceration, frequently seen at endoscopy, to deep chronic penetrating ulcers. This does not minimise the importance of acute stress ulceration. These ulcers can both perforate and bleed.

For many years, the cause of peptic ulceration remained an

enigma. When comparing groups of patients with duodenal and prepyloric peptic ulcers with normal subjects, gastric acid levels are higher, but the overlap is very considerable. Patients with gastric ulceration have relatively normal levels of gastric acid secretion. As peptic ulceration will occur in the presence of very high acid levels, such as those found in patients with a gastrinoma (Zollinger–Ellison syndrome), and as all ulcers can be healed in the absence of acid, it is clear that acid is important. In patients with a gastrinoma it may be the only aetiological factor, but this is not the case in the majority of patients. As with many diseases, genetic factors may be involved to a limited degree and social stress has also been falsely implicated (Asher).

It is now widely accepted that infection with *H. pylori* and the consumption of NSAIDs are the most important factors in the development of peptic ulceration. In combination, *H. pylori* and NSAIDs act synergistically to promote ulcer development and ulcer bleeding. Cigarette smoking predisposes to peptic ulceration and increases the relapse rate after treatment, with either gastric antisecretory agents or, in the past, elective surgery. Multiple other factors may be involved in transition between the superficial and the deep penetrating chronic ulcer, but they are of lesser importance.

Duodenal ulceration

Incidence

There have been marked changes in the last two decades in the demography of patients presenting with duodenal ulceration in the West. First, even before the introduction of H_2 -receptor antagonists, the incidence of duodenal ulceration and the frequency of elective surgery for the condition were falling. This trend has continued and now, in the West, dyspeptic patients presenting with a duodenal ulcer at gastroscopy are uncommon. In part, this may relate to the widespread use of gastric antisecretory agents and *H. pylori* eradication therapy for patients with dyspepsia. Second, the peak incidence is now in a much older age group than previously and, although it is still more common in men, the difference is less marked. These changes mirror the changes, at least in part, in the epidemiology of *H. pylori* infection. In Eastern Europe, the disease remains common and, from having been uncommon in some developing nations, it is now observed more frequently. Again, the relationship with *H. pylori* appears convincing.

Pathology

Most occur in the first part of the duodenum (Figures 63.12 and 63.13). A chronic ulcer penetrates the mucosa and into the muscle coat, leading to fibrosis. The fibrosis causes deformities such as pyloric stenosis. When an ulcer heals, a scar can be observed in the mucosa. Sometimes there may be more than one duodenal ulcer. The situation in which there is both a posterior and an anterior duodenal ulcer is referred to as 'kissing ulcers'. Anteriorly placed ulcers tend to perforate and, in contrast, posterior duodenal ulcers tend to bleed, sometimes by eroding into the gastroduodenal artery. Occasionally, the ulceration may be so extensive that the entire duodenal cap is ulcerated and devoid of mucosa. With respect to the giant duodenal ulcer,

Richard Asher, 1912–1969, physician, the Central Middlesex Hospital, London, UK. Ridiculed the concept that the stress of modern living caused peptic ulceration by pointing out that the same claim was made for syphilis! It is an interesting coincidence that both diseases have strong aetiological associations with spiral organisms.

Figure 63.12 Duodenal ulcer at gastroduodenoscopy (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

Figure 63.13 Duodenal ulcer shown by barium meal.

malignancy in this region is so uncommon that under normal circumstances surgeons can be confident that they are dealing with benign disease, even though from external palpation it may not appear so. In the stomach the situation is different.

Histopathology

Microscopically, destruction of the muscular coat is observed and the base of the ulcer is covered with granulation tissue, the arteries in this region showing the typical changes of endarteritis obliterans. Sometimes the terminations of nerves can be seen among the fibrosis. The pathological appearances of the healing ulcer must be carefully interpreted as some of the epithelial downgrowths can be misinterpreted as invasion. This is unlikely to be important in duodenal ulcers when malignancy rarely, if ever, occurs, but it is much more important with gastric ulcers.

Robert Milton Zollinger, 1903–1992, Professor of Surgery, the Ohio State University, Columbus, OH, USA.

Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, WI, USA.

Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at the Ohio State University.

Gastric ulcers

Incidence

As with duodenal ulceration, *H. pylori* and NSAIDs are the important aetiological factors. Gastric ulceration is also associated with smoking; other factors are of lesser importance.

There are marked differences between the populations afflicted by chronic gastric ulceration compared with duodenal ulceration. First, gastric ulceration is substantially less common than duodenal ulceration. The sex incidence is equal and the population with gastric ulcers tends to be older. It is more prevalent in low socioeconomic groups and is considerably more common in the developing world than in the West.

Pathology

This is essentially similar to that of a duodenal ulcer, except that gastric ulcers tend to be larger. Fibrosis, when it occurs, may result in the now rarely seen hourglass contraction of the stomach. Large chronic ulcers may erode posteriorly into the pancreas and, on other occasions, into major vessels such as the splenic artery. Less commonly, they may erode into other organs such as the transverse colon. Chronic gastric ulcers are much more common on the lesser curve (especially at the incisura angularis; Figures 63.14 and 63.15) than on the greater curve and, even when high on the lesser curve, they tend to be at the boundary between the acid-secreting and the non-acid-secreting epithelia. With atrophy of parietal cell mass, non-acid-secreting epithelium migrates up the lesser curvature.

Malignancy in gastric ulcers

Chronic duodenal ulcers are not associated with malignancy and, in contrast, gastric ulcers are. Widely varying estimates are made of the incidence of gastric malignancy in gastric ulcers. The reason for this is that the authors reporting such diverse incidences are describing different clinical situations. Two clinical extremes must be distinguished to understand this problem properly. First, there is the situation in which a benign chronic gastric ulcer undergoes malignant transformation. This is known to happen, albeit rarely. The contrasting clinical extreme is

Figure 63.14 Benign incisural gastric ulcer shown at gastroscopy (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

Figure 63.15 Benign gastric ulcer shown on barium meal. (a) Radiograph. (b) Diagrammatic outline.

the patient identified as having an ulcer in the stomach, either endoscopically or on contrast radiology, which is assessed as benign but biopsies reveal malignancy. In this situation the patient does not have, and probably never has had, chronic peptic ulceration in the stomach but has presented with an ulcerated cancer. This situation is common, although whether a lesion found in the stomach is described as being benign or malignant on clinical grounds depends very much on the skill and experience of the endoscopist or radiologist.

It is fundamental that any gastric ulcer should be regarded as being malignant, no matter how classic the features of a benign gastric ulcer. Multiple biopsies should always be taken, perhaps as many as ten well-targeted biopsies, before an ulcer can be tentatively accepted as being benign. Even then it is important that further biopsies are taken while the ulcer is healing and when healed. Modern antisecretory agents can frequently heal the ulceration associated with gastric cancer but, clearly, are ineffective in treating the malignancy itself. At operation, even experienced surgeons may have difficulty distinguishing between the gastric cancer and a benign ulcer. Operative strategies differ so radically that it is essential, if at all possible, that a confident diagnosis is made before operation. If, at operation, it is determined that the ulcer is probably benign it should, nonetheless, be excised, in totality if possible, and submitted for histological examination. It is not known whether a patient's survival is compromised by this approach if the ulcer turns out to be malignant on biopsy, as convincing data are not available.

Other peptic ulcers

The prepyloric gastric ulcer was in the past difficult to treat, a problem overcome with the introduction of proton pump inhibitors. Pyloric channel ulcers are similar to duodenal ulcers. Both prepyloric and pyloric ulcers may be malignant, and biopsy is essential. Stomal ulcers occur after a gastroenterostomy or a gastrectomy of the Billroth II type. The ulcer is usually found on the jejunal side of the stoma.

Clinical features of peptic ulcers

Although many textbooks try to create differences in the clinical features of gastric and duodenal ulceration, detailed

analysis has shown that they cannot be differentiated on the basis of symptoms. The demographic characteristics of groups of patients with gastric and duodenal ulceration do differ but this does not allow discrimination.

Pain

The pain is epigastric, often described as gnawing and may radiate to the back. Eating may sometimes relieve the discomfort. The pain is normally intermittent rather than intractable.

Periodicity

One of the classic features of untreated peptic ulceration is periodicity. Symptoms may disappear for weeks or months to return again. This periodicity may be related to the spontaneous healing of the ulcer.

Vomiting

While this occurs, it is not a notable feature unless stenosis has occurred.

Alteration in weight

Weight loss or, sometimes, weight gain may occur. Patients with gastric ulceration are often underweight but this may precede the occurrence of the ulcer.

Bleeding

All peptic ulcers may bleed. The bleeding may be chronic and presentation with microcytic anaemia is not uncommon. All such patients should be investigated with endoscopy. Acute presentation with haematemesis and melaena is discussed below under Haematemesis and melaena.

Clinical examination

Examination of the patient may reveal epigastric tenderness but, except in extreme cases (for instance gastric outlet obstruction), there is unlikely to be much else to find.

Investigation of the patient with suspected peptic ulcer

Gastroduodenoscopy

This is the investigation of choice in the management of suspected peptic ulceration and in the hands of a well-trained operator is highly sensitive and specific.

In the stomach, any abnormal lesion should be multiple biopsied, and in the case of a suspected benign gastric ulcer numerous biopsies must be taken in order to exclude, as far as possible, the presence of a malignancy. Commonly, biopsies of the antrum will be taken to see whether there is histological evidence of gastritis and a CLO test performed to determine the presence of *H. pylori*. A 'U' manoeuvre should be performed to exclude ulcers around the gastro-oesophageal junction. This is important as the increasing incidence of cancer at the gastro-oesophageal junction requires that all mucosal abnormalities in this region should undergo multiple biopsy. Similarly, if a stoma is present, for instance after gastroenterostomy or Billroth II gastrectomy, it is important to enter both afferent and efferent loops. Almost all stomal ulcers will be very close to the junction between the jejunal and gastric mucosa. Attention should be given to the pylorus to note whether there is any prepyloric or pyloric channel ulceration, and also whether it is deformed, which is often

the case with chronic duodenal ulceration. In the duodenum, care must be taken to view all of the first part. It is not infrequent for an ulcer to be just beyond the pylorus and easily overlooked.

Treatment of peptic ulceration

The vast majority of uncomplicated peptic ulcers are treated medically. Surgical treatment of uncomplicated peptic ulceration has decreased markedly since the 1960s and is now seldom performed in the West. Surgical treatment was aimed principally at reducing gastric acid secretion and, in the case of gastric ulceration, removing the diseased mucosa. When originally devised, medical treatment also aimed to reduce gastric acid secretion, initially using the highly successful H_2 -receptor antagonist and, subsequently, proton pump inhibitors. This has now largely given way to eradication therapy.

Medical treatment

It is reasonable that a doctor managing a patient with an uncomplicated peptic ulcer should suggest modifications to the patient's lifestyle, particularly the cessation of cigarette smoking. This advice is rarely followed and pharmacological measures form the mainstay of treatment.

H_2 -receptor antagonists and proton pump inhibitors

H_2 -antagonists (Black) revolutionised the management of peptic ulceration. Most duodenal ulcers and gastric ulcers can be healed by a few weeks of treatment with these drugs provided that they are taken and absorbed. There remained, however, a group of patients who were relatively refractory to conventional doses of H_2 -receptor antagonists. This is largely now irrelevant as proton pump inhibitors can effectively render a patient achlorhydric and all benign ulcers will heal using these drugs, the majority within 2 weeks. Symptom relief is impressively rapid, most patients being asymptomatic within a few days. Like H_2 -antagonists, proton pump inhibitors are safe and relatively devoid of serious side effects. The problem with all gastric antisecretory agents is that following cessation of therapy relapse is almost universal.

Eradication therapy

Eradication therapy is now routinely given to patients with peptic ulceration, and this is described earlier in this chapter. Evidence suggests that if a patient has a peptic ulcer and *H. pylori* is the principal aetiological factor (essentially the patient not taking NSAIDs), then complete eradication of the organism will cure the disease and reinfection as an adult is uncommon. Eradication therapy is therefore the mainstay of treatment for peptic ulceration. It is extremely economical by comparison with prolonged courses of antisecretory agents or surgery. It is also considerably safer than surgical treatment.

There are some patients with peptic ulcers in whom eradication therapy may not be appropriate and this includes patients with NSAID-associated ulcers. Such patients should avoid these drugs if possible and, if not, they should be co-prescribed with a potent antisecretory agent. Similarly, patients with stomal ulceration are not effectively treated with eradication therapy and

Sir James Whyte Black, 1924–2002, Professor of Analytical Pharmacology, King's College Hospital Medical School, London, UK, introduced beta-blockers and H_2 receptor antagonists. For this work he shared the 1988 Nobel Prize for Physiology or Medicine with Gertrude Bion and George Hitchings.

require prolonged prescription of antisecretory agents. Patients with Zollinger–Ellison syndrome should be treated in the long term with proton pump inhibitors unless the tumour can be adequately managed by surgery.

Ulcers that fail to heal

The introduction of antisecretory agents and effective treatments for *H. pylori* have revolutionized the management of peptic ulcers. Despite these advances, peptic ulceration fails to heal in a small minority of patients. Endoscopic re-evaluation should be regarded as mandatory to confirm healing of gastric ulcers. Furthermore, endoscopy permits the differentiation between a refractory ulcer and persistent symptoms despite ulcer healing. The most common cause of failed healing is persistent *H. pylori* infection. Biopsies should be repeated at the time of endoscopy as false-negative results with breath tests may be expected soon after eradication therapy and serum antibody titres may not fall for six months after successful eradication. Failure of eradication is usually due to poor compliance or bacterial resistance and bacteriological culture will guide further attempts at *H. pylori* eradication. The ingestion of NSAIDs should once again be addressed. A diagnosis of Zollinger–Ellison syndrome (described in detail below under Zollinger–Ellison syndrome) should be suspected in *H. pylori* negative, non-NSAID-related peptic ulceration and serum gastrin levels should be measured.

Surgical treatment of uncomplicated peptic ulceration

From its peak in the 1960s, the incidence of surgery for uncomplicated peptic ulceration has fallen markedly, to the extent that peptic ulcer surgery is now of little more than historical interest. A description of operations used in the treatment of peptic ulcers is still necessary because surgery is occasionally employed for the complicated ulcer and, in addition, many patients are left suffering from the consequences of the more destructive operations.

Operations for duodenal ulceration

Duodenal ulcer surgery (rationale)

Procedures devised for the treatment of duodenal ulcers have the common aim of excluding the damaging effects of acid from the duodenum. This has been achieved by diversion of the acid away from the duodenum, reducing the secretory potential of the stomach, or both. All of the operations devised achieved their aim to some extent, but with varying degrees of morbidity, mortality and postoperative side effects. There is now no role for acid-reducing operations in the routine management of peptic ulcer disease but, occasionally, operations which involve gastrectomy have to be performed in the emergency situation. In addition, many patients have had such operations performed and suffer from the sequelae. Hence it is important for the clinician to understand the anatomical and physiological consequences of surgery. The operations are described in historical sequence.

Billroth II gastrectomy

The first successful gastrectomy was performed by Billroth in January 1881, and Wolfler performed the first gastroenterostomy in the same year. The original Billroth operations consisted of a gastric resection with gastroduodenal anastomosis (Billroth I

technique) (Figure 63.16). The Billroth II operation was devised more by accident than design (Figure 63.17). A gastroenterostomy (Figure 63.18) was performed on a gravely ill patient with a pyloric cancer, who was not expected to survive. Contrary to expectations, the patient improved and the stomach distal to the anastomosis was resected. It soon became evident that the use of a gastrojejunal anastomosis after gastric resection could be safer and easier than the Billroth I procedure, and it became popular and effective in the surgical treatment of duodenal ulcer. Because of its disadvantages, such as higher operative mortality and morbidity, it has not been used for many years in the patient with an uncomplicated ulcer, but it is still used occasionally in the treatment of a complicated ulcer with a 'difficult' duodenum. In Billroth II gastrectomy, or its close relation Polya gastrectomy, the antrum and distal body of the stomach are

Figure 63.16 Billroth I gastrectomy. The lower half of the stomach is removed and the cut stomach anastomosed to the first part of the duodenum.

Figure 63.17 Billroth II. Two-thirds of the stomach removed, the duodenal stump is closed and the stomach anastomosed to the jejunum.

Table 63.2 Operative mortality, side effects and incidence of recurrence following duodenal ulcer operations.

Operation	Operative mortality (%)	Significant side effects (%)	Recurrent ulceration (%)
Gastrectomy	1–2	20–40	1–4
Gastroenterostomy alone	<1	10–20	50
Truncal vagotomy and drainage	<1	10–20	2–7
Selective vagotomy and drainage	<1	10–20	5–10
Highly selective vagotomy	<0.2	<5	2–10
Truncal vagotomy and antrectomy	1	10–20	1

mobilised by opening the greater and lesser omentum and dividing the gastroepiploic arteries, right gastric artery and the left gastric artery arcade at the limit of the resection. The duodenum is closed off either by suture or using staples, sometimes with difficulty in patients with a very deformed duodenum. Various techniques are available to close the difficult duodenum and, in *extremis*, a catheter may be placed in the duodenal stump, the duodenum closed around it and a catheter brought out through the abdominal wall. Following resection, the distal end of the stomach is narrowed by the closure of the lesser curve aspect of the remnant. The greater curve aspect is then anastomosed, usually in a retrocolic fashion, to the jejunum leaving as short an afferent loop as feasible (Figure 63.17). Even when well performed, this procedure has an operative mortality rate of a few per cent and morbidity is not unusual. A common cause of morbidity is leakage from the duodenal stump, which is particularly associated with kinking of the afferent loop. Leakage from the gastrojejunal anastomosis is unusual unless it is under tension or the stomach has been devascularised during the mobilisation. The incidence of side effects following gastrectomy is considerable, as shown in Table 63.2. Recurrence of the ulcer at the stoma is uncommon but can occur, especially as this procedure is traditionally not combined with the vagotomy.

Gastrojejunostomy

Because of the potential for mortality after gastrectomy, the use of gastrojejunostomy alone in the treatment of duodenal ulceration was developed (Figure 63.18). Reflux of alkali from the small bowel into the stomach reduced duodenal acid exposure and was often successful in healing the ulcer. However, because the jejunal loop was exposed directly to gastric acid, stomal ulceration was extremely common, hence the procedure in isolation was ineffective.

Truncal vagotomy and drainage

Truncal vagotomy was first introduced in 1943 by Dragstedt and, for many years, combined with drainage, was the mainstay of treatment of duodenal ulceration (Figure 63.19). The principle of the operation is that section of the vagus nerves, which are critically involved in the secretion of gastric acid, reduces the maximal acid output by approximately 50 per cent. Because the vagal nerves are motor to the stomach, denervation of the antropyloroduodenal segment results in gastric stasis in a sub-

Lester Reynolds Dragstedt, 1893–1975, Professor of Surgery, Chicago, IL, USA. He was a physiologist to start with and later became a surgeon. His physiological mind made him consider that vagotomy would be a treatment for peptic ulcer. Accordingly, he performed the first vagotomy in 1943.

Figure 63.18 Gastroenterostomy. The jejunum is anastomosed to the posterior, dependent, wall of the stomach.

stantial proportion of patients on whom truncal vagotomy alone is performed. This was first noted by Dragstedt, who did not perform a drainage procedure when he first introduced the operation. The most popular drainage procedure is the Heineke–Mikulicz pyloroplasty (Figure 63.20). It is simple to perform and involves the longitudinal section of the pyloric ring. The incision is closed transversely. Gastrojejunostomy (Figure 63.18) was the alternative drainage procedure to pyloroplasty. This is performed through opening the lesser sac and performing an anastomosis between the most dependent part of the antrum and the first jejunal loop. An isoperistaltic anastomosis was most commonly performed. The operation of truncal vagotomy and drainage is substantially safer than gastrectomy (Table 63.2). However, the side effects of surgery are, in fact, little different from those that follow gastrectomy.

Highly selective vagotomy

In 1968, Johnston and Amdrup independently devised the operation of highly selective vagotomy in which only the parietal cell mass of the stomach was denervated (Figure 63.21). This proved to be the most satisfactory operation for duodenal ulceration, with a low incidence of side effects and acceptable recurrence rates when performed to a high technical standard. This operation became the ‘gold standard’ for operations on duodenal ulceration in the 1970s. The operative mortality was

Walther Hermann Heineke, 1834–1901, surgeon of Erlangen, Germany.

lower than any other definitive operation for duodenal ulceration, in all probability because the gastrointestinal tract was not opened during this procedure. The unpleasant effects of peptic ulcer surgery were largely avoided, although loss of receptive relaxation of the stomach did occur, leading to epigastric fullness and sometimes mild dumping. However, the severe symptoms that occur after other more destructive gastric operations did not occur. It is often said that recurrent ulceration is the

Achilles heel of this operation although, when performed well, recurrence was no more common than after truncal vagotomy. The operation disappeared from routine use with the advent of antisecretory agents and eradication therapy.

Truncal vagotomy and antrectomy

For completeness, this operation should be mentioned as at one stage it was popular in the USA. In addition to a truncal vagotomy, the antrum of the stomach is removed, thus removing the source of gastrin, and the gastric remnant is joined to the duodenum. The recurrence rates after this procedure are exceedingly low. However, the operative mortality is higher than after vagotomy and drainage (Table 63.2) and the incidence of unpleasant side effects is similar.

Operations for gastric ulcer

In contrast with duodenal ulcer surgery, when the principal objective was to reduce duodenal acid exposure, in gastric ulceration the diseased tissue is usually removed as well. This has the advantage that malignancy can then be confidently excluded. As with duodenal ulceration, such surgery is not now performed except for complications of gastric ulcer.

Billroth I gastrectomy

This was the standard operation (Figure 63.16) for gastric ulceration until medical treatments became prevalent. The distal stomach is mobilised and resected in the same way as in the Billroth II gastrectomy. This resection should include the ulcer that is usually situated on the lesser curve. The cut edge of the remnant is then partially closed from the lesser curve aspect, leaving a stoma at the greater curve aspect, which should be similar in size to the duodenum. Reconstruction may be facilitated by mobilising the duodenum using Kocher's manoeuvre. The incidence of recurrent ulceration after this operation is low, but it carries with it the morbidity and mortality associated with any gastric resection.

Sequelae of peptic ulcer surgery

There are a number of sequelae of peptic ulcer surgery, which include recurrent ulceration, small stomach syndrome, bilious vomiting, early and late dumping, diarrhoea and malignant transformation. These sequelae principally follow from the more destructive operations that are now seldom performed. However, a substantial number of patients suffer from side effects from operations undertaken in the past. Approximately 30 per cent of patients can expect to suffer a degree of dysfunc-

tion following peptic ulcer surgery (Table 63.2) and, in about 5 per cent of such patients, the symptoms will be intractable.

Recurrent ulceration

Although mentioned first, this is by far the easiest problem to treat. Just as all peptic ulcers will heal with potent antisecretory agents, so will ulcers that are recurrent after ulcer surgery.

As with other peptic ulcers, recurrent ulcers may present with complications, particularly bleeding and perforation. In this respect, the complication of gastrojeuno-colic fistula requires a particular mention. In this rare condition, the anastomotic ulcer penetrates into the transverse colon. Patients suffer from diarrhoea that is severe and follows every meal. They have foul breath and may vomit formed faeces. Severe weight loss and dehydration are rapid in onset, and for this reason the condition may be mistaken for malignancy. The major factor producing the nutritional disturbance is the severe contamination of the jejunum with colonic bacteria. A number of imaging techniques can be used to detect the fistula, most commonly CT with oral contrast or indeed a barium enema. Endoscopy may not convincingly demonstrate the fistula and, in about one-half of such cases, the barium meal will not reveal the problem. The treatment of gastrocolic fistula consists of first correcting the dehydration and malnutrition and then performing revisional surgery.

Small stomach syndrome

Early satiety follows most ulcer operations to some degree, including highly selective vagotomy. In this latter circumstance, although there is no anatomical disturbance of the stomach there is loss of receptive relaxation. Fortunately, this problem does tend to get better with time and revisional surgery is not necessary.

Bile vomiting

Bile vomiting can occur after any form of vagotomy with drainage or gastrectomy. Commonly, the patient presents with vomiting a mixture of food and bile or sometimes some bile alone after a meal. Often, eating will precipitate abdominal pain and reflux symptoms are common. Bile chelating agents can be tried but are usually ineffective. In intractable cases, revisional surgery may be indicated. The nature of that revisional surgery depends very much on the original operation. Following gastrectomy, Roux-en-Y diversion is probably the best treatment. In patients with a gastroenterostomy, this can be taken down and, in most circumstances a small pyloroplasty can be performed. In patients with a pyloroplasty, reconstruction of the pylorus has been attempted but, in general terms, the results of this operation have been rather poor. Antrectomy and Roux-en-Y reconstruction may be the better option.

Early and late dumping

Although considered together because the symptoms are similar, early and late dumping have different aetiologies. A common feature, however, is early rapid gastric emptying. Many patients have both early and late dumping.

Early dumping

Early dumping consists of abdominal and vasomotor symptoms that are found in about 10 per cent of patients following gastrectomy or vagotomy and drainage. It also affects a small percentage of patients following highly selective vagotomy due

to the loss of receptive relaxation of the stomach. The small bowel is filled with foodstuffs from the stomach, which have a high osmotic load, and this leads to the sequestration of fluid from the circulation into the gastrointestinal tract. This can be observed by the rise in the packed cell volume while the symptoms are present. All of the symptoms shown in Table 63.3 can be related to this effect on the gut and the circulation.

The principal treatment is dietary manipulation. Small, dry meals are best, and avoiding fluids with a high carbohydrate content also helps. Fortunately, following operation, the syndrome tends to improve with time. For some reason, however, there is a group of patients who suffer intractable dumping regardless of any of these measures. The somatostatin analogue octreotide given before meals has been shown to be useful in some individuals and the long-acting preparation may also be useful. However, this treatment can lead to the development of gallstones and it does not help the diarrhoea from which many patients with dumping also suffer.

Revisional surgery may be occasionally required. In patients with a gastroenterostomy, the drainage may be taken down or, in the case of a pyloroplasty, repaired. Alternatively, antrectomy with Roux-en-Y reconstruction is often effective, although the procedure is of greater magnitude; following gastrectomy, it is the revisional procedure of choice.

Table 63.3 Features of early and late dumping.

	Early	Late
Incidence	5–10%	5%
Relation to meals	Almost immediate	Second hour after meal
Durations of attack	30–40 minutes	30–40 minutes
Relief	Lying down	Food
Aggravated by	More food	Exercise
Precipitating factor	Food, especially carbohydrate-rich and wet	As early dumping
Major symptoms	Epigastric fullness, sweating, light-headedness, tachycardia, colic, sometimes diarrhoea	Tremor, faintness, prostration

Late dumping

This is reactive hypoglycaemia. The carbohydrate load in the small bowel causes a rise in the plasma glucose, which, in turn, causes insulin levels to rise, causing a secondary hypoglycaemia. This can be easily demonstrated by serial measurements of blood glucose in a patient following a test meal. The treatment is essentially the same as for early dumping. Octreotide is very effective in dealing with this problem.

Postvagotomy diarrhoea

This can be the most devastating symptom to afflict patients having peptic ulcer surgery. Most patients will suffer some looseness of bowel action to some degree (with the exception of highly selective vagotomy) but, in about 5 per cent, it may be

intractable. Despite much investigation, the precise aetiology of the problem is uncertain. It is related, to some degree, to rapid gastric emptying. In all probability, the denervation of the upper gastrointestinal tract as a result of the vagotomy is also important. Exaggerated gastrointestinal peptide responses may also aggravate the condition.

The diarrhoea in postvagotomy patients may take several forms. It may be severe and explosive, the patient experiencing a considerable degree of urgency. The patients sometimes describe the diarrhoea as feeling like passing boiling water. At the other extreme, some patients only have minor episodes of diarrhoea, which are not as directly related to food.

Many authors regard diarrhoea and dumping as being essentially the same problem. However, many patients with severe diarrhoea do not have any of the other symptoms of dumping and likewise some patients with dumping do not experience any significant diarrhoea.

The condition is difficult to treat. The patient should be managed as for early dumping and antidiarrhoeal preparations may be of some value. Octreotide is not effective in this condition and the results of revisional surgery are too unpredictable to make this an attractive treatment option.

Malignant transformation

Many large studies now confirm that operations such as gastrectomy or vagotomy and drainage are independent risk factors for the development of gastric cancer. The increased risk appears to be approximately four times that of the control population.

It is not difficult to understand the increased incidence of gastric cancer, as bile reflux gastritis, intestinal metaplasia and gastric cancer are linked. The lag phase between operation and the development of malignancy is at least ten years. Highly selective vagotomy does not seem to be associated with an increased incidence of gastric cancer in the long term.

Nutritional consequences

Nutritional disorders are more common after gastrectomy than after vagotomy and drainage. Weight loss is common after gastrectomy and the patient may, in fact, never return to their original weight. Nutritional advice advising the taking of small meals is often more useful. Anaemia may be due to either iron or vitamin B12 deficiency.

Iron-deficiency anaemia occurs after both gastrectomy and vagotomy and drainage and is probably multifactorial in origin. Reduced iron absorption is probably the most important factor, although the loss of blood from the gastric mucosa may also be important. Vitamin B12 deficiency is prone to occur after total gastrectomy. However, because of the very large vitamin B12 stores that most patients have, this may be very late in occurring. Vitamin B12 supplementation after total gastrectomy is essential. Rarely, vitamin B12 deficiency may occur after lesser forms of gastrectomy. In such patients the cause is probably a combination of reduced intrinsic factor production and also the fact that some patients have bacterial colonisation, which results in the destruction of the vitamin B12 in the gut.

Bone disease is seen principally after gastrectomy, and mainly in women. The condition is essentially indistinguishable from the osteoporosis commonly seen in postmenopausal women. It is only the frequency and magnitude of the disorder that distinguish it. Treatment is with dietary supplementation, calcium and vitamin D, and exercise.

Gallstones

The development of gallstones is strongly associated with truncal vagotomy. Following truncal vagotomy, the biliary tree, as well as the stomach, is denervated, leading to stasis and hence stone formation. Patients developing symptomatic gallstones will require cholecystectomy. However, this may induce or worsen other postpeptic ulcer surgery syndromes such as bilious vomiting and postvagotomy diarrhoea.

The complications of peptic ulceration

The common complications of peptic ulcer are perforation, bleeding and stenosis. Bleeding and stenosis are considered below in the relevant sections.

Perforated peptic ulcer

Epidemiology

Despite the widespread use of gastric antisecretory agents and eradication therapy, the incidence of perforated peptic ulcer has changed little. However, there has been a considerable change in the epidemiology of perforated peptic ulcer in the West over the last two decades. Previously, most patients were middle aged, with a ratio of 2:1 of male:female. With time, there has been a steady increase in the age of the patients suffering this complication and an increase in the numbers of females, such that perforations now occur most commonly in elderly female patients. NSAIDs appear to be responsible for most of these perforations.

Clinical features

The classic presentation of perforated duodenal ulcer is instantly recognisable (Figure 63.22). The patient, who may have a history of peptic ulceration, develops sudden onset severe generalised abdominal pain due to the irritant effect of gastric acid on the peritoneum. Although the contents of an acid-producing stomach are relatively low in bacterial load, bacterial peritonitis supervenes over a few hours, usually accompanied by a deterioration in the patient's condition. Initially, the patient may be shocked with a tachycardia but a pyrexia is not usually observed until some hours after the event. The abdomen exhibits a board-like rigidity and the patient is disinclined to move because of the pain. The abdomen does not move with respiration. Patients with this form of presentation need an operation, without which the patient will deteriorate with a septic peritonitis.

This classic presentation of the perforated peptic ulcer is observed less commonly than in the past. Very frequently, the

Figure 63.22 A sketch of Mr Hamilton Bailey watching for abdominal movement on respiration. In the case of a classically presenting perforated ulcer, the abdominal movement is restricted or absent.

elderly patient who is taking NSAIDs will have a less dramatic presentation, perhaps because of the use of potent anti-inflammatory drugs (steroids). The board-like rigidity seen in the abdomen of younger patients may also not be observed and a higher index of suspicion is necessary to make the correct diagnosis. In other patients, the leak from the ulcer may not be massive. They may present only with pain in the epigastrium and right iliac fossa as the fluid may track down the right paracolic gutter. Sometimes perforations will seal owing to the inflammatory response and adhesion within the abdominal cavity, and so the perforation may be self-limiting. All of these factors may combine to make the diagnosis of perforated peptic ulcer difficult.

By far the most common site of perforation is the anterior aspect of the duodenum. However, the anterior or incisural gastric ulcer may perforate and, in addition, gastric ulcers may perforate into the lesser sac, which can be particularly difficult to diagnose. These patients may not have obvious peritonitis.

Investigations

An erect plain chest radiograph will reveal free gas under the diaphragm in an excess of 50 per cent of cases with perforated peptic ulcer (Figure 63.23) but CT imaging is more accurate (see below). All patients should have serum amylase performed, as distinguishing between peptic ulcer, perforation and pancreatitis can be difficult. Measuring the serum amylase, however, may not remove the diagnostic difficulty. It can be elevated following perforation of a peptic ulcer although, fortunately, the levels are not usually as high as the levels commonly seen in acute pancreatitis. Several other investigations are useful if doubt remains. A CT scan will normally be diagnostic in both conditions.

Treatment

The initial priorities are resuscitation and analgesia. Analgesia should not be withheld for fear of removing the signs of an intra-abdominal catastrophe. In fact, adequate analgesia makes the clinical signs more obvious. It is important, however, to titrate the analgesic dose. Following resuscitation, the treatment is principally surgical. Laparotomy is performed, usually through an upper midline incision if the diagnosis of perforated peptic ulcer can be made with confidence. This is not always possible and hence it may be better to place a small incision around

Figure 63.23 Plain abdominal radiograph of a perforated ulcer, showing air under the diaphragm.

the umbilicus to localise the perforation with more certainty. Alternatively, laparoscopy may be used. The most important component of the operation is a thorough peritoneal toilet to remove all of the fluid and food debris. If the perforation is in the duodenum it can usually be closed by several well-placed sutures, closing the ulcer in a transverse direction as with a pyloroplasty. It is important that sufficient tissue is taken in the suture to allow the edges to be approximated, and the sutures should not be tied so tight that they tear out. It is common to place an omental patch over the perforation in the hope of enhancing the chances of the leak sealing. If the perforation is difficult to close primarily, it is frequently possible to seal the leak with an omental patch alone, and many surgeons now employ this strategy for all perforations. When securing the omental patch it is important not to tie the sutures too tight so as to obliterate the omental blood supply. Gastric ulcers should, if possible, be excised and closed, so that malignancy can be excluded. Occasionally, a patient is seen who has a massive duodenal or gastric perforation such that simple closure is impossible; in these patients a Billroth II gastrectomy or subtotal gastrectomy with Roux-en-Y reconstruction are useful operations.

All patients should be treated with systemic antibiotics in addition to a thorough peritoneal lavage. In the past, many surgeons performed definitive procedures such as either truncal vagotomy and pyloroplasty or, more recently and probably more successfully, highly selective vagotomy during the course of an operation for a perforation. Studies show that in well-selected patients and in expert hands this is a very safe strategy. However, nowadays, surgery is confined to first-aid measures most commonly, and the peptic ulcer is treated medically as described earlier in this chapter. Following operation, gastric antisecretory agents should be started immediately.

Perforated peptic ulcers can often be managed by minimally invasive techniques if the expertise is available. The principles of operation are, however, the same; thorough peritoneal toilet is performed and the perforation is closed by intracorporeal suturing. Whatever technique is used, it is important that the stomach is kept empty postoperatively by nasogastric suction, and that gastric antisecretory agents are commenced to promote healing of the residual ulcer.

A great deal has been written about the conservative management of perforated ulcer. Some writers say that virtually all patients can be managed conservatively, whereas most surgeons have difficulty in understanding how a patient who is ill with widespread peritonitis and who has food debris widely distributed through the abdominal cavity will improve without an operation. However, undoubtedly, there are patients who have small leaks from a perforated peptic ulcer and relatively mild peritoneal contamination, who may be managed with intravenous fluids, nasogastric suction and antibiotics. These patients are in the minority. A number of factors have been associated with poor outcome after perforated peptic ulcer, including:

- delay in diagnosis (>24 hours)
- medical comorbidities
- shock
- increasing age (>75).

There is little evidence to advocate the conservative management of patients who exhibit any of these characteristics.

Patients who have suffered one perforation may suffer another one. Therefore, they should be managed aggressively to

ensure that this does not happen. In patients with *Helicobacter*-associated ulcers, eradication therapy is appropriate. Life-long treatment with proton pump inhibitors is a reasonable option, especially in those who have to continue with NSAID treatment (Summary box 63.4).

HAEMATEMESIS AND MELAENA

Upper gastrointestinal haemorrhage remains a major medical problem with an incidence of over 100/100 000 per year in Western practice that increases with increasing age. Haemorrhage is strongly associated with NSAID use. Despite improvements in diagnosis and the proliferation in treatment modalities over the last few decades, an in-hospital mortality of 5–10 per cent can be expected. This rises to 33 per cent when bleeding is first observed in patients who are hospitalised for other reasons. In patients in whom the cause of bleeding can be found, the most common causes are peptic ulcer, erosions, Mallory–Weiss tear and bleeding oesophageal varices (Table 63.4).

Table 63.4 Causes of upper gastrointestinal bleeding.

Condition	%
Ulcers	60
Oesophageal	6
Gastric	21
Duodenal	33
Erosions	26
Oesophageal	13
Gastric	9
Duodenal	4
Mallory–Weiss tear	4
Oesophageal varices	4
Tumour	0.5
Vascular lesions, e.g. Dieulafoy's disease	0.5
Others	5

Whatever the cause, the principles of management are identical. First, the patient should be adequately resuscitated and, following this, the patient should be investigated urgently to determine the cause of the bleeding. Only then should treatment of a definitive nature be instituted. For any significant gastrointestinal bleed, intravenous access should be established and, for those with severe bleeding, central venous pressure monitoring should be set up and bladder catheterisation performed. Blood should be cross-matched and the patient transfused as clinically indicated, usually when >30 per cent of blood volume has been lost. There is no evidence for the use of intravenous proton pump inhibitors prior to endoscopy. As a general rule, most gastrointestinal bleeding will stop, albeit temporarily, but there are sometimes instances when this is not the case. In these circumstances, resuscitation, diagnosis and treatment should be carried out simultaneously. There are occasions when life-

saving manoeuvres have to be undertaken without the benefit of an absolute diagnosis. For instance, in patients with known oesophageal varices and uncontrollable bleeding, a Sengstaken–Blakemore tube may be inserted before an endoscopy has been carried out. This practice is not to be encouraged, except *in extremis*. In some patients, bleeding is secondary to a coagulopathy. The most important current causes of this are liver disease and inadequately controlled warfarin therapy. In these circumstances the coagulopathy should be corrected, if possible, with fresh-frozen plasma or concentrated clotting factors.

Upper gastrointestinal endoscopy should be carried out by an experienced operator as soon as practicable after the patient has been stabilised. In patients in whom the bleeding is relatively mild, endoscopy may be carried out on the morning after admission. In all cases of severe bleeding it should be carried out immediately. A number of scoring systems have been advocated for the assessment of rebleeding and death after upper gastrointestinal haemorrhage. Perhaps the most useful of these is the Rockall score. This can be used in a pre-endoscopy format to stratify patients to safe early discharge and postendoscopy it can relatively accurately predict rebleeding and death.

Bleeding peptic ulcers

The epidemiology of bleeding peptic ulcers exactly mirrors that of perforated ulcers. In recent years, the population affected has become much older and the bleeding is commonly associated with the ingestion of NSAIDs. Diagnosis can normally be made endoscopically, although occasionally the nature of the blood loss precludes accurately identifying the lesion. However, the more experienced the endoscopist, the less likely this is to be a problem.

Medical and minimally interventional treatments

Medical treatment has limited efficacy. All patients are commonly started on either an H_2 -antagonist or a proton pump antagonist, and recent evidence confirms the benefit of proton pump inhibitor administration to prevent rebleeding after endoscopy. Furthermore, meta-analysis of studies suggests that tranexamic acid, an inhibitor of fibrinolysis, may reduce overall mortality.

Therapeutic endoscopy can achieve haemostasis in approximately 70 per cent of cases, with the best evidence supporting a combination of adrenaline injection with heater probe and/or clips. Therapeutic endoscopy will probably never be effective in patients who are bleeding from large vessels and with which the majority of the mortality is associated.

In patients where the source of bleeding cannot be identified or in those who rebleed after endoscopy, angiography with transcatheter embolisation may offer a valuable alternative to surgery in expert centres. The risk of significant ischaemia following embolisation is low because of the rich collateral blood supply of the stomach and duodenum. The surgeon should be mindful that rescue surgery after failed embolisation is associated with poor outcome and it may be advantageous to proceed directly to surgery.

Surgical treatment

Criteria for surgery are well worked out. A patient who continues to bleed requires surgical treatment. The same applies to a

George Kenneth Mallory, born 1926, Professor of Pathology, Boston University, Boston, MA, USA.

Soma Weiss, 1898–1942, Professor of Medicine, Harvard University Medical School, Boston, MA, USA.

Robert William Sengstaken, born 1923, surgeon, Garden City, New York, NY, USA.

Arthur Hendley Blakemore, Associate Professor of Surgery, the Columbia College of Physicians and Surgeons, New York, NY, USA.

Sengstaken and Blakemore originally described the tube in 1950.

significant rebleed. Patients with a visible vessel in the ulcer base, a spurting vessel or an ulcer with a clot in the base are statistically likely to require surgical treatment to stop the bleeding. Elderly and unfit patients are more likely to die as a result of bleeding than younger patients. Ironically, they should have early surgery. A patient who has required more than six units of blood in general needs surgical treatment.

The aim of the operation is to stop the bleeding. The advent of endoscopy has greatly helped in the management of upper gastrointestinal bleeding as a surgeon can usually be confident about the site of bleeding prior to operation. The most common site of bleeding from a peptic ulcer is the duodenum. In tackling this, it is essential that the duodenum is fully mobilised. This should be done before the duodenum is opened as it makes the ulcer much more accessible and also allows the surgeon's hand to be placed behind the gastroduodenal artery, which is commonly the source of major bleeding. Following mobilisation, the duodenum, and usually the pylorus, is opened longitudinally as in a pyloroplasty (Figure 63.20). This allows good access to the ulcer, which is usually found posteriorly or superiorly. Accurate haemostasis is important and can be achieved initially by direct pressure. It is the vessel within the ulcer that is bleeding and this should be controlled using well-placed sutures on a small round-bodied needle that under-run the vessel. The placing of more and more inaccurately positioned sutures is counterproductive. Following under-running, it is often possible to close the mucosa over the ulcer. The pyloroplasty is then closed with interrupted sutures in a transverse direction as in the usual fashion. In a giant ulcer the first part of the duodenum may be destroyed making primary closure impossible. In this circumstance one should proceed to subtotal gastrectomy with Roux-en-Y reconstruction. The duodenal stump may then be closed using the Nissen technique with T-tube drainage.

The principles of management of bleeding gastric ulcers are essentially the same. The stomach is opened at an appropriate position anteriorly and the vessel in the ulcer under-run. If the ulcer is not excised then a biopsy of the edge needs to be taken to exclude malignant transformation. Sometimes the bleeding is from the splenic artery and if there is a lot of fibrosis present then the operation may be challenging. However, most patients can be managed by conservative surgery. Gastrectomy for bleeding has been widely practised in the past, but is associated with a high perioperative mortality even if the incidence of recurrent bleeding is less.

Bearing in mind that most patients nowadays are elderly and unfit, the minimum surgery that stops the bleeding is probably optimal. Acid can be inhibited by pharmacological means and appropriate eradication therapy will prevent ulcer recurrence. Definitive acid-lowering surgery is not now required. Patients on long-term NSAIDs can be managed as outlined earlier.

Stress ulceration

This commonly occurs in patients with major injury or illness, who have undergone major surgery or who have major comorbidity. Many such patients are found in intensive care units. There seems little doubt that the incidence of this problem has reduced in recent years due to the widespread use of prophylaxis. Acid inhibition and the nasogastric or oral administration of sucralfate has been shown to reduce the incidence of stress ulceration. There is no doubt that it is far better to prevent this condition than to try to treat it once it occurs. Endoscopic

means of treating stress ulceration may be ineffective and operation may be required. The principles of management are the same as for the chronic ulcer.

Gastric erosions

Erosive gastritis has a variety of causes, especially NSAIDs. Fortunately, most such bleeding settles spontaneously, but when it does not it can be a major problem to treat. In general terms, although there is a diffuse erosive gastritis, there is one (or more) specific lesion that has a significant-sized vessel within it. This should be dealt with appropriately, preferably endoscopically, but sometimes surgery is necessary.

Mallory-Weiss tear

This is a longitudinal tear at the gastro-oesophageal junction, which is induced by repetitive and strenuous vomiting. Doubtless, many such lesions occur and do not cause bleeding. When it is a cause of haematemesis, the lesion may often be missed as it can be difficult to see as it is just below the gastro-oesophageal junction, a position that can be difficult for the inexperienced endoscopist. Occasionally, these lesions continue to bleed and require surgical treatment. Often the situation arises in which the surgeon does not have guidance from the endoscopists as regards the site of bleeding, and a high index of suspicion in such circumstances is important. The experienced surgeon will perform on-table endoscopy prior to embarking on surgery. The stomach is opened by longitudinal gastrotomy and the upper section is carefully inspected. It is normally possible to palpate the longitudinal mucosal tear with a little induration at the edges, which gives a clue to the lesion's location. Under-running is all that is required.

Dieulafoy's disease

This is essentially a gastric arterial venous malformation that has a characteristic histological appearance. Bleeding due to this malformation is one of the most difficult causes of upper gastrointestinal bleeding to treat. The lesion itself is covered by normal mucosa and, when not bleeding, it may be invisible. If it can be seen while bleeding, all that may be visible is profuse bleeding coming from an area of apparently normal mucosa. If this occurs, the cause is instantly recognisable. If the lesion can be identified endoscopically there are various means of dealing with it, including injection of sclerosant and endoscopic clips. If it is identified at operation then only a local excision is necessary. Occasionally, a lesion is only recognised after gastrectomy and sometimes not even then. The pathologist, as well as the endoscopist, may have difficulty in finding it.

Tumours

All of the gastric tumours described below may present with chronic or acute upper gastrointestinal bleeding. Bleeding is not normally torrential but can be unremitting. Gastric stromal tumours commonly present with bleeding and have a characteristic appearance, as the mucosa breaks down over the tumour in the gastric wall (Figure 63.24). Whatever the nature, the tumours should be dealt with as appropriate.

Portal hypertension and portal gastropathy

The management of bleeding gastric varices is very challenging. Fortunately, most bleeding from varices is oesophageal and this

Figure 63.24 Smooth muscle tumour of the stomach, with ulceration.

is much more amenable to sclerotherapy, banding and balloon tamponade. Gastric varices may also be injected, although this is technically more difficult. Banding can also be used, again with difficulty. The gastric balloon of the Sengstaken–Blakemore tube can be used to arrest the haemorrhage if it is occurring from the fundus of the stomach or gastro-oesophageal junction. Octreotide is a somatostatin analogue that reduces portal pressure in patients with varices, and trials suggest that it is of value in arresting haemorrhage in these patients, although its overall effect on mortality remains in doubt. Glypressin is also said to be of use.

Most surgeons prefer to avoid acute surgery on bleeding varices as, in contrast with elective operations for portal hypertension, acute shunts are attended by considerable operative mortality. For this reason the acute TIPSS procedure (trans-jugular intrahepatic portosystemic shunt), which is described in Chapter 65, can be an extremely useful, although technically demanding, procedure.

Portal gastropathy

Portal gastropathy is essentially the same disease process as described above. The mucosa is affected by the increased portal pressure and may exude blood, even in the absence of well-developed visible varices. The treatment is as above.

Aortic enteric fistula

This diagnosis should be considered in any patient with haematemesis and melaena that cannot be otherwise explained. Contrary to expectation, the bleeding from such patients is not always massive, although it can be. Very often there is nothing much to distinguish between the bleeding from the aortic enteric fistula and any other recurrent upper gastrointestinal bleeding. The vast majority of patients will have had an aortic graft and, in the absence of this, the diagnosis is unlikely. However, it is occasionally seen in patients with an untreated aortic aneurysm. A well-performed CT scan will commonly allow the diagnosis to be made with certainty. The condition should be managed by an expert vascular surgeon as, whether secondary or primary, the morbidity and mortality are high.

GASTRIC OUTLET OBSTRUCTION

The two common causes of gastric outlet obstruction are gastric cancer (see below) and pyloric stenosis secondary to peptic ulceration. Previously, the latter was more common. Now, with the decrease in the incidence of peptic ulceration and the advent of potent medical treatments, gastric outlet obstruction should be considered malignant until proven otherwise, at least in the West.

The term ‘pyloric stenosis’ is normally a misnomer. The stenosis is seldom at the pylorus. Commonly, when the condition is due to underlying peptic ulcer disease, the stenosis is found in the first part of the duodenum, the most common site for a peptic ulcer. True pyloric stenosis can occur due to fibrosis around a pyloric channel ulcer. However, in recent years, the most common cause of gastric outlet obstruction has been gastric cancer. In this circumstance the metabolic consequences may be somewhat different from those of benign pyloric stenosis because of the relative hypochlorhydria found in patients with gastric cancer (Summary box 63.5).

Summary box 63.5

Gastric outlet obstruction

- Gastric outlet obstruction is most commonly associated with long-standing peptic ulcer disease and gastric cancer
- The metabolic abnormality of hypochlorhaemic alkalosis is usually only seen with peptic ulcer disease and should be treated with isotonic saline with potassium
- Endoscopic biopsy is essential to determine whether the cause of the problem is malignancy
- Aggressive medical therapy for peptic ulcer disease often leads to resolution
- Endoscopic dilatation of the gastric outlet may be effective in the less severe cases of benign stenosis
- Operation is frequently required, with a drainage procedure being performed for benign disease and appropriate resectional surgery if malignant

Clinical features

In benign gastric outlet obstruction there is usually a long history of peptic ulcer disease. Nowadays, as most patients with peptic ulcer symptoms are treated medically, it is easy to understand why the condition is becoming much less common. In some patients the pain may become unremitting and in other cases it may largely disappear. The vomitus is characteristically unpleasant in nature and is totally lacking in bile. Very often it is possible to recognise foodstuff taken several days previously. The patient commonly complains of losing weight, and appears unwell and dehydrated. When examining the patient, it may be possible to see the distended stomach and a succussion splash may be audible on shaking the patient’s abdomen.

Metabolic effects

These are most interesting as the metabolic consequences of benign pyloric stenosis are unique. The vomiting of hydrochloric acid results in hypochlorhaemic alkalosis. Initially, the sodium and potassium may be relatively normal. However, as dehydration progresses, more profound metabolic abnormalities arise,

partly related to renal dysfunction. Initially, the urine has a low chloride and high bicarbonate content, reflecting the primary metabolic abnormality. This bicarbonate is excreted along with sodium, and so with time the patient becomes progressively hyponatraemic and more profoundly dehydrated. Because of the dehydration, a phase of sodium retention follows and potassium and hydrogen are excreted in preference. This results in the urine becoming paradoxically acidic and hypokalaemia ensues. Alkalosis leads to a lowering in the circulating ionised calcium, and tetany can occur.

Management

Treating the patient involves correcting the metabolic abnormality and dealing with the mechanical problem. The patient should be rehydrated with intravenous isotonic saline with potassium supplementation. Replacing the sodium chloride and water allows the kidney to correct the acid–base abnormality. Following rehydration, it may become obvious that the patient is also anaemic, the haemoglobin being spuriously high on presentation.

It is notable that the metabolic abnormalities may be less if the obstruction is due to malignancy, as the acid–base disturbance is less pronounced.

The stomach should be emptied using a wide-bore gastric tube. A large nasogastric tube may not be sufficiently large to deal with the contents of the stomach, and it may be necessary to pass an orogastric tube and lavage the stomach until it is completely emptied. This then allows investigation of the patient with endoscopy and contrast radiology. Biopsy of the area around the pylorus is essential to exclude malignancy. The patient should also have a gastric antisecretory agent, initially given intravenously to ensure absorption.

Early cases may settle with conservative treatment, presumably as the oedema around the ulcer diminishes as the ulcer is healed. Traditionally, severe cases are treated surgically, usually with a gastroenterostomy rather than a pyloroplasty. Endoscopic treatment with balloon dilatation has been practised and may be most useful in early cases. However, this treatment is not devoid of problems. Dilating the duodenal stenosis may result in perforation. The dilatation may have to be performed several times and may not be successful in the long term. Occasionally, duodenal stent insertion will be considered in specialist centres.

Other causes of gastric outlet obstruction

Adult pyloric stenosis

This is a rare condition and its relationship to the childhood condition is unclear, although some patients have a long history of problems with gastric emptying. It is commonly treated by pyloroplasty rather than pyloromyotomy.

Pyloric mucosal diaphragm

The origin of this rare condition is unknown. It usually does not become apparent until middle age. When found, simple excision of the mucosal diaphragm is all that is required.

GASTRIC POLYPS

A number of conditions manifest as gastric polyps. Their main importance is that they may actually represent early gastric cancer. Biopsy is essential.

The most common type of gastric polyp is metaplastic. These are associated with *H. pylori* infection and regress following eradication therapy. Inflammatory polyps are also common. Fundic gland polyps deserve particular attention. They seem to be associated with the use of proton pump inhibitors and are also found in patients with familial polyposis. None of the above polypoid lesions has proven malignant potential. True adenomas have malignant potential and should be removed, but they account for only 10 per cent of polypoid lesions. Gastric carcinoids arising from the ECL cells are seen in patients with pernicious anaemia and usually appear as small polyps.

GASTRIC CANCER

Carcinoma of the stomach is a major cause of cancer mortality worldwide. Its prognosis tends to be poor, with cure rates little better than 5–10 per cent, although better results are obtained in Japan, where the disease is common. Gastric cancer is actually an eminently curable disease provided that it is detected at an appropriate stage and treated adequately. It rarely disseminates widely before it has involved the lymph nodes and, therefore, there is an opportunity to cure the disease prior to dissemination. Early diagnosis is therefore the key to success with this disease. Unfortunately, the late presentation of many cases is the cause of the poor overall survival figures. The only treatment modality able to cure the disease is resectional surgery (Summary box 63.6).

Summary box 63.6

Gastric cancer

- Gastric cancer is one of the most common causes of cancer death in the world
- The outlook is generally poor, owing to the advanced stage of the tumour at presentation
- Better results are obtained in Japan, which has a high population incidence, screening programmes and a high-quality surgical treatment
- The aetiology of gastric cancer is multifactorial, but *H. pylori* is an important factor for distal but not proximal gastric cancer
- Early gastric cancer is associated with very high cure rates
- Gastric cancer can be classified into intestinal and diffuse types, the latter having a worse prognosis
- In the West, proximal gastric cancer is now more common than distal cancer and is usually of the diffuse type
- Spread may be by lymphatics, blood, transcoelomic or direct, but distant metastases are uncommon in the absence of lymph node involvement
- The treatment of curable cases is by radical surgery and removal of the second tier of nodes (around the principal arterial trunks) may be advantageous
- Gastric cancer is chemosensitive and chemotherapy improves survival in patients having surgery for the condition and in advanced disease

Incidence

There are marked variations in the incidence of gastric cancer worldwide. In the UK, it is approximately 15/100 000 per year, in the USA 10/100 000 per year and in Eastern Europe 40/100 000 per year. In Japan, the disease is much more

common, with an incidence of approximately 70/100 000 per year, and there are small geographical areas in China where the incidence is double that in Japan. These underlying epidemiological data make it clear that this is an environmental disease. In general, men are more affected by the disease than women and, as with most solid-organ malignancies, the incidence increases with age.

At present, marked changes are being observed in the West in terms of the incidence and site of gastric cancer and the population affected, changes that to date have not been observed in Japan. First, the incidence of gastric cancer is continuing to fall at about 1 per cent per year. This reduction exclusively affects carcinoma arising in the body and distal stomach. In contrast, there appears to be an increase in the incidence of carcinoma in the proximal stomach, particularly the oesophagogastric junction. Carcinoma of the distal stomach and body of the stomach is most common in low socioeconomic groups, whereas the increase in proximal gastric cancer seems to affect principally higher socioeconomic groups. Proximal gastric cancer does not seem to be associated with *H. pylori* infection, in contrast with carcinoma of the body and distal stomach.

Aetiology

Gastric cancer is a multifactorial disease (Correa). Epidemiological studies point to a role for *H. pylori*, although there is argument about how important this factor is. Studies reveal a correlation between the incidence of gastric cancer in various populations and the prevalence of *H. pylori* infection, but other factors are also important. There is insufficient evidence at the moment to support eradication programmes in asymptomatic patients who are infected with *Helicobacter*, with a view to reducing the population incidence of gastric cancer. However, clinical trials may subsequently change this view. As mentioned above, *Helicobacter* seems to be principally associated with carcinoma of the body and distal stomach rather than the proximal stomach. As *Helicobacter* is associated with gastritis, gastric atrophy and intestinal metaplasia, the association with malignancy is perhaps not surprising.

Several other risk factors have been identified as being important in the aetiology of gastric cancer. Patients with pernicious anaemia and gastric atrophy are at increased risk, as are those with gastric polyps. Patients who have had peptic ulcer surgery, particularly those who have had drainage procedures such as Billroth II or Polya gastrectomy, gastroenterostomy or pyloroplasty, are at approximately four times the average risk. Presumably, duodenogastric reflux and reflux gastritis are related to the increased risk of malignancy in these patients. Intestinal metaplasia is a risk factor. Carcinoma is associated with cigarette smoking and dust ingestion from a variety of industrial processes. Diet appears to be important, as illustrated by the often quoted example of the change in the incidence of gastric cancer in Japanese families living in the USA. The high incidence of gastric cancer in some pockets in China is probably environmental and probably diet related. The ingestion of substances such as spirits may induce gastritis and, in the long term, cancer. Excessive salt intake, deficiency of antioxidants and exposure to *N*-nitroso compounds are also related. The aetiology of proximal gastric cancer remains an enigma. It is not associated with *Helicobacter* but is associated with obesity and higher socioeconomic status. Genetic factors are also important but imperfectly elucidated (see below).

Clinical features

The features of advanced gastric cancer are usually obvious. However, curable gastric cancer has no specific features to distinguish it symptomatically from benign dyspepsia. The key to improving the outcome of gastric cancer is early diagnosis and, although in Japan there is a screening programme, most curable cases are picked up by the liberal use of gastroscopy in patients with dyspepsia. In the West it is much more difficult as the population incidence is much lower. Hence the cost-effectiveness of performing gastroscopy for mild dyspeptic symptoms is low. However, a high index of suspicion is necessary as only endoscopic patients with symptoms of advanced cancer is unlikely to be beneficial as such patients are not surgically curable. It is important to note that gastric antisecretory agents will improve the symptoms of gastric cancer so the disease should be excluded preferably before therapy is started.

In advanced cancer, early satiety, bloating, distension and vomiting may occur. The tumour frequently bleeds, resulting in iron deficiency anaemia. Obstruction leads to dysphagia, epigastric fullness or vomiting. With pyloric involvement the presentation may be of gastric outlet obstruction, although the alkalosis is usually less pronounced or absent compared with when duodenal ulceration leads to obstruction. In recent years, gastric outlet obstruction is more commonly associated with malignancy than benign disease. Non-metastatic effects of malignancy are seen, particularly thrombophlebitis (Trousseau's sign) and deep venous thrombosis. These features result from the effects of the tumour on thrombotic and haemostatic mechanisms.

Site

The proximal stomach is now the most common site for gastric cancer in the West. Because so many malignancies occur at the oesophagogastric junction, and because the lower oesophagus is also a very common site of adenocarcinoma, it is artificial to separate the stomach from the oesophagus. Therefore, it is best to consider the whole of the upper gastrointestinal tract from the cricopharyngeus to the pylorus. The incidence of cancer at these various sites is shown in Figure 63.25. It can be seen that just under 60 per cent of all of the malignancies occurring in the oesophagus and stomach occur in proximity to the oesophagogastric junction. Adenocarcinoma at this site has doubled in incidence in the UK over the last 30 years. This high prevalence of proximal gastric cancer is not seen in Japan, where distal cancer still predominates, as it does in most of the rest of the world.

Pathology

The most useful classification of gastric cancer is the Lauren classification. In this system there are principally two forms of gastric cancer: intestinal gastric cancer and diffuse gastric cancer. In intestinal gastric cancer, the tumour resembles a carcinoma elsewhere in the tubular gastrointestinal tract and forms polypoid tumours or ulcers. It probably arises in areas of intestinal metaplasia. In contrast, diffuse gastric cancer infiltrates deeply into the stomach without forming obvious mass lesions, but spreads widely in the gastric wall. Not surprisingly, this has a much worse prognosis. A small proportion of gastric cancers are of mixed morphology.

Armand Trousseau, 1801–1867, physician, Hôtel Dieu, Paris. The sign led him to suspect that he had gastric cancer himself. He actually had pancreatic cancer which was diagnosed at postmortem.

Figure 63.25 The incidence of cancer in the various parts of the upper gastrointestinal tract in the UK. OG, oesophagogastric.

Gastric cancer can be divided into early gastric cancer and advanced gastric cancer. Early gastric cancer is defined as cancer limited to the mucosa and submucosa with or without lymph node involvement (T1, any N). The classification is shown in Figures 63.26 and 63.27. This can be either protruding, superficial or excavated in the Japanese classification. This type of cancer is eminently curable, and even early gastric cancers associated with lymph node involvement have five-year survival rates in the region of 90 per cent. In Japan, approximately one-third of gastric cancers diagnosed are in this stage. However, in the UK it is uncommon to detect gastric cancers at this stage. A

Figure 63.26 Early gastric cancer, Japanese classification.

number of reasons probably still account for this. First, because gastric cancer is less common in the UK, dyspeptic patients are not always referred for endoscopy at an appropriate stage. Second, endoscopists are unfamiliar with the appearances of early gastric cancer and in all probability many such cases are missed.

Advanced gastric cancer involves the muscularis. Its macroscopic appearances have been classified by Bormann into four types (Figures 63.28 and 63.29). Types III and IV are commonly incurable.

The molecular pathology of gastric cancer

Although the molecular pathology of gastric cancer is less well worked out than colorectal cancer, several genetic events

Figure 63.27 Early gastric cancer. (a) Type I; (b) type IIa; (c) type III (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

have been established, some of which have clinical relevance. Mutation or loss of heterozygosity in the APC gene or in β -catenin, an associated gene, is found in approximately 50 and 30 per cent, respectively, of cases of intestinal type cancer. APC mutations are found less frequently in diffuse gastric cancer and not at all in patients with β -catenin mutations. In contrast, another related molecule, E-cadherin, is mutated in 50 per cent of cases of diffuse cancer. In some families, inherited diffuse gastric cancer has been shown to be related to a germline mutation in E-cadherin.

Errors in DNA replication manifesting as microsatellite instability (MSI) have been demonstrated in approximately 15 per cent of cases, with little distinction between the intestinal or diffuse types. This genetic phenotype is associated with the inherited cancer syndrome hereditary non-polyposis colorectal cancer syndrome (HNPCC) or the Lynch syndrome. However, most cases of MSI are a result of an acquired mutation in the tumour itself. These findings serve to illustrate that there are important differences between the two types of cancer at a molecular level.

Inactivation of *p53*, a tumour-suppressor gene, is found in around 30 per cent of both intestinal and diffuse gastric cancer.

Several growth factor receptors are overexpressed/amplified in gastric cancer; these include c-Met, k-Sam and c-ErbB2. Similarly, several growth factors may be overexpressed, including transforming growth factor α , the epidermal growth factor and vascular endothelial growth factor (VEGF).

Lastly, loss of heterozygosity at the *bcl-2* gene, an inhibitor of apoptosis, is associated with intestinal-type cancer.

These genetic changes may be involved in the familial predisposition to gastric cancer. Well-known syndromes such as HNPCC have gastric cancer as part of their spectrum.

Staging

The International Union Against Cancer (UICC) staging system is shown in Table 63.5. Important changes have been made in the seventh edition of the TNM staging system that are worthy of discussion. In an attempt to reflect the current evidence base and to improve outcome prediction for individual patients all gastric tumours whose epicentre is within 5 cm of the gastro-oesophageal junction and extend into the oesophagus are now classified according to the oesophageal system. Tumours whose epicentre is within 5 cm of the gastro-oesophageal junction but do not extend into the oesophagus, and all other gastric cancers are staged using the revised gastric staging system. In addition, any tumour that perforates the serosa is now classified as T4 disease.

Spread of carcinoma of the stomach

No better example of the various modes by which carcinoma spreads can be given than the case of stomach cancer. It is important to note that distant spread is unusual before the disease spreads locally, and distant metastases are uncommon in the absence of lymph node metastases. The intestinal and diffuse types of gastric cancer spread differently. The diffuse type spreads via the submucosal and subserosal lymphatic plexus and it penetrates the gastric wall at an early stage.

Direct spread

The tumour penetrates the muscularis, serosa and ultimately adjacent organs such as the pancreas, colon and liver.

Table 63.5 International Union Against Cancer (UICC) staging of gastric cancer.

T1	Tumour involves lamina propria, submucosa		
	T1a lamina propria		
	T1b submucosa		
T2	Tumour invades muscularis propria		
T3	Tumour involves subserosa		
T4a	Tumour perforates serosa		
T4b	Tumour invades adjacent organs		
N0	No lymph nodes		
N1	Metastasis in 1–2 regional nodes		
N2	Metastasis in 3–6 regional nodes		
N3a	Metastasis in 7–15 regional nodes		
N3b	Metastasis in more than 15 regional nodes		
M0	No distant metastasis		
M1	Distant metastasis (this includes peritoneum and distant lymph nodes)

IIIC	T4a	N3	M0
	T4b	N2–3	M0
IV	Any T	Any N	M1

Lymphatic spread

This is by both permeation and emboli to the affected tiers (see below) of nodes. This may be extensive, the tumour even appearing in the supraclavicular nodes (Troisier's sign). Unlike malignancies such as breast cancer, nodal involvement does not imply systemic dissemination.

Figure 63.28 Borrmann classification of advanced gastric cancer.

Figure 63.29 Advanced gastric cancer. (a) Type I; (b) type II; (c) type III; (d) type IV (linitis plastica) (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

Blood-borne metastases

These occur first to the liver and subsequently to other organs, including lung and bone. This is uncommon in the absence of nodal disease.

Transperitoneal spread

This is a common mode of spread once the tumour has reached the serosa of the stomach and indicates incurability. Tumours can manifest anywhere in the peritoneal cavity and commonly give rise to ascites. Advanced peritoneal disease may be palpated either abdominally or rectally as a tumour 'shelf'. The ovaries may sometimes be the sole site of transcoelomic spread (Krukenberg's tumours). Tumour may spread via the abdominal cavity to the umbilicus (Sister Joseph's nodule). Transperitoneal spread of gastric cancer can be detected most effectively by laparoscopy and cytology.

Lymphatic drainage of the stomach

Understanding the lymphatic drainage of the stomach is the key to comprehending the radical surgery of gastric cancer. The lymphatics of the antrum drain into the right gastric lymph node superiorly, and right gastroepiploic and subpyloric lymph nodes inferiorly. The lymphatics of the pylorus drain into the right gastric suprapyloric nodes superiorly and the subpyloric lymph nodes situated around the gastroduodenal artery inferiorly. The efferent lymphatics from suprapyloric lymph nodes converge on the para-aortic nodes around the coeliac axis, whereas the efferent lymphatics from the subpyloric lymph nodes pass up to the main superior mesenteric lymph nodes situated around the origin of the superior mesenteric artery. The lymphatic vessels related to the cardiac orifice of the stomach communicate freely with those of the oesophagus.

The prognosis of operable cases of carcinoma of the stomach depends on whether or not there is histological evidence of regional lymph node involvement. Retrograde (downwards) spread may occur if the upper lymphatics are blocked. In Japan, the lymph node dissection is highly advanced and the Japanese Research Society for Gastric Cancer has assigned a number to each lymph node station to aid the pathological staging (Figure 63.30). Many centres in the West now perform surgery that involves a radical lymphadenectomy but, in other centres, both the staging and surgery are less developed.

Operability

It is important that patients with incurable disease are not subjected to radical surgery that cannot help them, hence the value of CT/PET and preoperative laparoscopy. Unequivocal evidence of incurability is haematogenous metastases, involvement of the distant peritoneum, N4 nodal disease and disease beyond the N4 nodes, and fixation to structures that cannot be removed. It is important to note that involvement of another organ per se does not imply incurability, provided that it can be removed. Controversies with respect to operability include N3 nodal involvement and involvement of the adjacent peritoneum, performed in Japan but seldom elsewhere. Curative resection should be considered on the remaining patients.

Friedrich Ernst Krukenberg, 1870–1946, ophthalmologist of Halle, Germany. In 1896 while studying pathology, he published his description of a fibrosarcoma of the ovary which became known as Krukenberg tumour of the ovary. He became an ophthalmologist who practised privately.

Figure 63.30 Lymphatic drainage of the stomach and nodal stations by the Japanese classification. (a) The anterior view of the stomach. (b) The posterior view.

Most operable patients should have neoadjuvant chemotherapy as described below as this improves survival.

Total gastrectomy

This is best performed through a long upper midline incision. The stomach is removed en bloc, including the tissues of the entire greater omentum and lesser omentum (Figure 63.31). In commencing the operation, the transverse colon is completely separated from the greater omentum. The dissection may then be commenced proximally or, more usually, distally. The subpyloric nodes are dissected and the first part of the duodenum is divided, usually with a surgical stapler. The hepatic nodes are dissected down to clear the hepatic artery; this dissection also includes the suprapyloric nodes. The right gastric artery is taken on the hepatic artery. The lymph node dissection is continued to the origin of the left gastric artery, which is divided flush with its origin. The dissection is continued along the splenic artery, taking all of the nodes at the superior aspect of the pancreas and accessible nodes in the splenic hilum. Separation of the stomach from the spleen, if this organ is not going to be removed, is carried out and this then allows access to the nodal tissues

Figure 63.31 Radical total gastrectomy. (a) Dissection of omentum off the transverse colon. (b) Exposure of the lesser sac. (c) Splenectomy. (d) Division and oversewing of the duodenum. (e) Dissection of the left gastric artery nodes (group 17). (f) Mobilisation of the oesophagus.

around the upper stomach and oesophagogastric junction. The oesophagus can then be divided at an appropriate point using a combination of stay sutures and a soft non-crushing clamp, usually of the right-angled variety. It is important that the resection margins are well clear of the tumour (>5 cm). Involvement of either proximal or distal resection margin carries an appalling prognosis and, if in doubt, frozen section should be performed. There is some controversy regarding the management of the spleen and distal pancreas in this procedure and this is discussed below.

Gastrointestinal continuity is reconstituted by means of a Roux loop. Other methods of reconstruction should be discouraged because of poor functional results. The alimentary limb of the Roux loop should be at least 50 cm long to avoid bile reflux oesophagitis. The simplest means of effecting the oesophagojejunostomy is to place a purse string in the cut end of the oesophagus and, using a circular stapler introduced through the blind end of the Roux loop, staple the end of the oesophagus onto the side of the Roux loop. The blind open end of the Roux loop may then be closed either with sutures or, alternatively, with a linear stapler. The anastomosis can also be fashioned end to end. The Roux loop may be placed in either an anticolic or retrocolic position. The jejunojunctionostomy is undertaken at a convenient point in the usual fashion (end to side, Figure 63.32).

There remains some controversy about the extent of the lymphadenectomy required for the optimal treatment of curable gastric cancer. In Japan, at least a D2 gastrectomy (removal of the

second-tier of nodes) is performed on all operable gastric cancer and some centres are practising more radical surgery (D3 and even D4 resections). Certainly, the results of surgical treatment stage for stage in Japan are much better than commonly reported in the West, and the Japanese contention is that the difference is principally related to the staging and the quality of the surgery. It is observed that the physical proportions of the average Japanese

Figure 63.32 Oesophagojejunostomy Roux-en-Y.

patient favour the performance of more radical procedures compared with the average patient in the West. However, radical lymphadenectomies above D2 have not been subjected to any randomised controlled trials. In the UK and Europe, randomised trials have been set up to compare D1 and D2 gastrectomy, but the results are difficult to interpret. One of the problems relates to standardisation of the operation. Overall, it seems that the oncological outcome may be better following a D2 gastrectomy, but this operation is associated with higher levels of morbidity and perioperative mortality. It is clear that most of this morbidity and mortality relates to the removal of the spleen with or without the distal pancreas. The traditional radical gastrectomy removes the spleen and distal pancreas en bloc with the stomach and, although this is indeed an adequate means of performing clearance of the lymph nodes around the splenic artery, there now seems little doubt that adding this substantially increases the complication rate. The Japanese D2 gastrectomy will commonly preserve spleen and pancreas and this practice has been widely adopted by specialist centres in the West.

The differentiation between a D1 and a D2 operation depends upon the tiers of nodes removed. Different tiers need to be removed depending on the positions of primary tumour and this is outlined in Table 63.6. In general, a D1 resection involves the removal of the perigastric nodes and a D2 resection involves the clearance of the major arterial trunks. In practice, the majority of specialist centres will perform a radical total gastrectomy, conserving the spleen and pancreas, with D2 lymphadenectomy sparing station 10 lymph nodes.

Subtotal gastrectomy

For tumours distally placed in the stomach, it appears unnecessary to remove the whole stomach. However, the operation is very similar to that of a total gastrectomy except that the proximal stomach is preserved, the blood supply being derived from the short gastric arteries. Following the resection, the simplest form of reconstruction is to close the stomach from the lesser curve, near the oesophagogastric junction, with either sutures or staples and then perform an anastomosis of the greater curve to the jejunum. Although this can be performed as in a Billroth II/Polya-type gastrectomy, this reconstruction may result in quite marked enterogastric reflux and bile reflux oesophagitis, and the preferred reconstruction is to perform the reconstruction using a Roux loop.

Palliative surgery

In patients suffering from significant symptoms of either obstruction or bleeding, palliative resection is appropriate. A palliative gastrectomy need not be radical and it is sufficient to remove the tumour and reconstruct the gastrointestinal tract. Sometimes it is impossible to resect an obstructing tumour in the distal stomach and other palliative procedures need to be considered, although the prognosis in such patients, even in the short term, is poor. A high gastroenterostomy is a poor operation that very frequently does not allow the stomach to empty adequately, but may produce the additional problem of bile reflux. A Roux loop with a wide anastomosis between the stom-

Table 63.6 The lymph node stations (see Figure 63.30) that need to be removed in a D1 (N1 nodes removed) or a D2 (N2 nodes removed) resection.

The nodes in stations 12–18 are not routinely removed in a D1 or D2 gastrectomy.

ach and jejunum may be a better option, although even this may not allow the stomach to empty particularly well. Gastric exclusion and oesophagojejunostomy is practised by some surgeons. For inoperable tumours situated in the cardia, either palliative intubation, stenting or another form of recanalisation can be used (Chapter 62). Recanalisation appears to offer better functional results.

Postoperative complications of gastrectomy

Radical gastrectomy is complex major surgery and predictably there is a large number of potential complications of the operation. Leakage of the oesophagojejunostomy should be uncommon in experienced hands. When it occurs it can often be managed conservatively as the Roux-en-Y reconstruction means that it is mainly saliva and ingested food that leaks. Some patients may establish a fistula from the wound or drain site and others may need radiological or surgically placed drains. It is unclear whether a nasoenteric tube should be used routinely. Many surgeons use such tubes routinely, but this is not supported by any evidence base. It is common practice to perform a water-soluble contrast swallow at 5–7 days after the operation to determine whether the anastomosis is intact, and finding a small radiological leak is not uncommon. It is unusual to detect a major leak in the absence of clinical signs. Physiological scoring systems to predict those patients likely to experience significant complications offer potential in this area.

As with any gastrectomy, leakage from the duodenal stump can occur. This is usually due to a degree of distal obstruction and care must be taken when performing the Roux-en-Y anastomosis that there is no kinking. Paraduodenal collections can be drained radiologically, which will often convert the collection into an external fistula. Biliary peritonitis requires a laparotomy and peritoneal toilet, and in this circumstance it is best to leave a Foley catheter in the duodenum to establish a controlled duodenal fistula. If it is established that there is no distal obstruction, or if any such obstruction is managed, then with time the fistula will close.

The presence of septic collections along with a very radical vascular dissection may lead to catastrophic secondary haemorrhage from the exposed or divided blood vessels. This situation may be very difficult to manage, whether or not reoperation or interventional radiology is employed.

Long-term complications of surgery

It is surprising that, considering the radical nature of the total gastrectomy, many patients, particularly the younger ones, have good functional results. However, most patients will have a reduced capacity, particularly in the short term. They need to be given detailed nutritional advice, the substance of which is to eat small meals and often, while the jejunum or small gastric remnant adapts. In fact, there is very little functional difference between patients who have a total gastrectomy and those who have a subtotal gastrectomy. Various attempts have been made to try and improve the short-term functional results by forming a jejunal pouch and attaching this to the oesophagus. Most surgeons do not perform this as in the long term there seems little functional advantage. It is surprising that these patients only infrequently suffer from the complications of gastric surgery, such as dumping and diarrhoea. Nutritional deficiencies may occur and the patient should be monitored with this in mind.

The loss of the parietal mass leads to vitamin B12 deficiency and replacement should be given routinely.

Outlook after surgical treatment

The outlook after surgical treatment varies considerably between the West and Japan. In Japan, approximately 75 per cent of patients will have a curative resection and, of these, the overall five-year survival rate will be in the region of 50–70 per cent. In contrast, in the West most series show that only 25–50 per cent of patients undergoing surgery will have a curative operation and the five-year survival rate in such patients is only about 25–30 per cent, although in some series it approaches Japanese levels. A combination of differences in staging and a higher standard of surgery in Japan probably accounts for the differences. Staging is clearly crucial when survival figures are being compared. The more thorough the staging, the higher the stage is likely to be and, therefore, stage for stage the outcome seems better in patients who are adequately staged pathologically. This phenomenon is termed 'stage migration'.

Other treatment modalities

Because of the failure of radical surgery to cure advanced gastric cancer, there has been an interest in the use of radiotherapy and chemotherapy.

Radiotherapy

The routine use of radiotherapy is controversial as the results of clinical trials are inconclusive. There are a number of radiosensitive tissues in the region of the gastric bed, which limits the dose that can be given. Radiotherapy has a role in the palliative treatment of painful bony metastases.

Chemotherapy

Gastric cancer may respond well to combination cytotoxic chemotherapy and neoadjuvant chemotherapy improves the outcome following surgery. Most patients therefore should have prior chemotherapy. There are a number of well-investigated regimes, but the best results are currently obtained using a combination of epirubicin, *cis*-platinum and infusional 5-FU or an oral analogue such as capecitabine. The same regimen is used as first line for patients with inoperable disease although oxaliplatin is being substituted for *cis*-platinum as it has fewer side effects. Second-line treatment using combinations which include taxotere are increasingly being used. Chemotherapy for advanced disease is palliative. Newer biological agents such as trastuzumab (Herceptin®) offer potential advantages to survival in the minority of patients (<20 per cent) with *HER2*-positive gastric cancer. However, the absolute survival advantages are small (approximately four months) and the cost of treatment is high. Nevertheless, trastuzumab has been approved for use in metastatic *HER2*-positive gastric cancer in the UK and European Union.

Pattern of relapse following surgical treatment

As might be expected, the most common site of relapse following radical gastrectomy is the gastric bed, representing inadequate extirpation of the primary tumour. Widespread nodal intraperitoneal metastases, distant nodal metastases and liver metastases are all common. Dissemination to the lung and bones usually only occurs after liver metastases are already established.

GASTROINTESTINAL STROMAL TUMOURS

Gastrointestinal stromal tumours (GIST) may arise in any part of the gastrointestinal tract but 50 per cent will be found in the stomach. Previously named leiomyoma and leiomyosarcoma, the term GIST is now used, recognising their particular distinct phenotype. They are tumours of mesenchymal origin and are observed equally commonly in males and females. The tumours are universally associated with a mutation in the tyrosine kinase *c-kit* oncogene. These tumours are sensitive to the tyrosine kinase antagonist imatinib, and an 80 per cent objective response rate can be observed. Tumours with mutations in exon 11 of *c-kit* are particularly sensitive to this drug. The biological behaviour of these tumours is unpredictable but size and mitotic index are the best predictors of metastasis. Peritoneal and liver metastases are most common but spread to lymph nodes extremely rare.

The incidence of the condition is unclear as small stromal tumours of the stomach are probably quite common and remain unnoticed. Clinically obvious tumours are considerably less common than gastric cancer. GIST comprise 1–3 per cent of all gastrointestinal neoplasia.

The only ways that many stromal tumours are recognised are either that the mucosa overlying the tumour ulcerates (see Figure 63.24), leading to bleeding, or that they are noticed incidentally at endoscopy. Because the mucosa overlying the tumour is normal, endoscopic biopsy can be uninformative unless the tumour has ulcerated. Targeted biopsy by endoscopic ultrasound is more helpful. Larger tumours present with non-specific gastric symptoms and, in many instances, they may be thought to be gastric cancer initially (Figure 63.33).

As the biological behaviour is difficult to predict, the best guide is to consider the size of the tumour. Tumours over 5 cm in diameter should be considered to have metastatic potential. If easily resectable, surgery is the primary mode of treatment. Smaller tumours can be treated by wedge excision although the

appropriate management of asymptomatic diminutive tumours found incidentally at endoscopy is unclear. Larger tumours may require a gastrectomy or duodenectomy (see Chapter 68) but lymphadenectomy is not required. Larger tumours which require multivisceral resection may be better treated with three to six months of imatinib prior to operation as this will usually radically reduce the size and vascularity of the tumours. Adjuvant imatinib for large resected tumours of high malignant potential should probably be continued indefinitely.

The prognosis of advanced metastatic GIST has been dramatically improved with imatinib chemotherapy but resection of metastases, especially from the liver, still has an important role.

GASTRIC LYMPHOMA

Gastric lymphoma is an interesting disease and some aspects of the management are controversial. It is first important to distinguish primary gastric lymphoma from involvement of the stomach in a generalised lymphomatous process. This latter situation is more common than the former. Unlike gastric carcinoma, the incidence of lymphoma seems to be increasing. Primary gastric lymphoma accounts for approximately 5 per cent of all gastric neoplasms.

Gastric lymphoma is the most common in the sixth decade and the presentation is no different from gastric cancer, the common symptoms being pain, weight loss and bleeding. Acute presentations of gastric lymphoma, such as haematemesis, perforation or obstruction, are not common. Primary gastric lymphomas are B cell derived, the tumour arising from the mucosa-associated lymphoid tissue (MALT). Primary gastric lymphoma remains in the stomach for a prolonged period before involving the lymph nodes. At an early stage, the disease takes the form of a diffuse mucosal thickening, which may ulcerate. Diagnosis is made as a result of the endoscopic biopsy and seldom on the basis of the endoscopic features alone, which are not specific.

Following diagnosis, adequate staging is necessary, primarily to establish whether the lesion is a primary gastric lymphoma or part of a more generalised process. CT scans of the chest and abdomen and bone marrow aspirate are required, as well as a full blood count.

Although the treatment of primary gastric lymphoma is somewhat controversial, it seems most appropriate to use surgery alone for the localised disease process. No benefit has been shown from adjuvant chemotherapy, although some oncologists contend that primary gastric lymphoma can be treated by chemotherapy alone. Chemotherapy alone is appropriate for patients with systemic disease.

Some of the more controversial aspects of gastric lymphoma concern the role of *H. pylori*. Lymphocytes are not found to any degree in normal gastric mucosa, but are found in association with *Helicobacter* infection. It has also been shown that early gastric lymphomas may regress and disappear when the *Helicobacter* infection is treated.

Gastric involvement with the diffuse lymphoma

These patients are treated with chemotherapy, sometimes with dramatic and rapid responses. Surgeons are frequently asked to deal with the complications of gastric involvement. The two common complications are bleeding and perforation. Both may occur at presentation, but more usually may follow the

Figure 63.33 Computed tomography of the upper abdomen showing a 3.5 cm gastrointestinal stromal tumour arising from the gastric wall.

chemotherapy when there is rapid regression and necrosis of the tumour. These operations can be technically very challenging and normally require gastrectomy.

DUODENAL TUMOURS

Benign duodenal tumours

Duodenal villous adenomas occur principally in the periampullary region. Although generally uncommon, they are often found in patients with familial adenomatous polyposis. The appearances are similar to those adenomas arising in the colon and, as they have malignant potential, they should be locally excised with histologically clear margins (Summary 63.7).

Summary box 63.7

Duodenal tumours

- Duodenal villous adenomas are commonly found around the ampulla of Vater and are premalignant
- Duodenal carcinoma is uncommon, but the most common site for adenocarcinoma is in the small intestine
- Both adenoma and carcinoma occur commonly in patients with familial polyposis and screening these patients is advised
- Pancreatic cancer is the most common cause of duodenal obstruction

Duodenal adenocarcinoma

Although uncommon, this is the most common site for adenocarcinoma arising in the small bowel. Most tumours originate in the periampullary region and commonly arise in pre-existing villous adenomas. Patients present with anaemia due to ulceration of the tumour or obstruction as the polypoid neoplasm begins to obstruct the duodenum. Direct involvement in the ampulla leads to obstructive jaundice. Histologically, the lesion is a typical adenocarcinoma and the metastases are commonly to regional lymph nodes and the liver. At presentation, about 70 per cent of the patients have resectable disease and for those who survive operation the five-year survival rate is in the region of 20 per cent, this approximately equating to cure. Poor prognostic features in the resected specimen include regional lymph node metastases, transmural involvement and perineural invasion. Curative surgical treatment will normally involve a pancreaticoduodenectomy (Whipple's procedure). Patients with familial polyposis, which is due to a mutation in the APC gene on chromosome 5, are predisposed to periampullary cancer, which is one of the most common causes of death in patients who have had their colon removed. Other duodenal malignancies include GISTs (see above) and neuroendocrine tumours.

Neuroendocrine tumours

A number of neuroendocrine neoplasms occurs in the duodenum. It is a common site for primary gastrinoma (Zollinger–Ellison syndrome). Non-functioning neuroendocrine tumours

Allen Oldfather Whipple, 1881–1963, Director of Surgical Services, The Presbyterian Hospital, and Professor of Surgery, the College of Physicians and Surgeons, New York, NY, USA.

(usually called carcinoid tumours) also occur but uncommonly in comparison to the ileum.

Zollinger–Ellison syndrome

This syndrome is mentioned here because the gastrin-producing endocrine tumour is often found in the duodenal loop, although it also occurs in the pancreas, especially the head. It is a cause of persistent peptic ulceration. Before the development of potent gastric antisecretory agents, the condition was recognised by the sometimes fulminant peptic ulceration which did not respond to gastric surgery short of total gastrectomy. It was also recognisable from gastric secretory studies in which the patient had a very high basal acid output but no marked response to pentagastrin, as the parietal cell mass was already nearly maximally stimulated by pathological levels of gastrin. The advent of proton pump inhibitors such as omeprazole has rendered this extreme endocrine condition fully controllable, but also less easily recognised.

Gastrinomas may be either sporadic or associated with the autosomal dominantly inherited multiple endocrine neoplasia (MEN) type I (in which a parathyroid adenoma is almost invariable). The tumours are most commonly found in the 'gastrinoma triangle' (Passaro) defined by the junction of the cystic duct and common bile duct superiorly, the junction of the second and third parts of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially (essentially the superior mesenteric artery). Many are found in the duodenal loop, presumably arising in the G cells found in Brunner's glands. It is extremely important that the duodenal wall is very carefully inspected endoscopically and also at operation. Very often all that can be detected is a small nodule that projects into the medial wall of the duodenum.

Even malignant sporadic gastrinomas may have a very indolent course. The palliative resection of liver metastases may be beneficial and liver transplantation is practised in some centres, as for other gut endocrine tumours, with reasonable long-term results. However, the minority of tumours found to the left of the superior mesenteric artery (outside the 'triangle') seems to have a worse prognosis, more having liver metastases at presentation. In MEN type I, the tumours may be multiple and the condition is incurable. Even in this situation, as with sporadic gastrinoma, surgical treatment should be employed to remove any obvious tumours and associated lymphatic metastases, as the palliation achieved may be good.

DUODENAL OBSTRUCTION

Duodenal obstruction in the adult is usually due to malignancy, and cancer of the pancreas is the most common cause. About one-fifth of patients with pancreatic cancer treated with endoscopic stenting will develop obstruction. Treatment is usually by gastroenterostomy but duodenal stenting is increasingly being used. In patients having a surgical biliary bypass for pancreatic cancer, gastric drainage may be necessary.

A variety of other malignancies can cause duodenal obstruction, including metastases from colorectal and gastric cancer. Primary duodenal cancer is much less common as a cause of obstruction than these other malignancies.

Annular pancreas may rarely cause duodenal obstruction. Obstruction usually follows an attack of pancreatitis and, on occasions, the obstruction may be mistaken for malignancy.

Arterioesenteric compression is an ill-defined condition

in which it is proposed that the fourth part of the duodenum is compressed between the superior mesenteric artery and the vertebral column; when it is convincingly demonstrated and causing weight loss, duodenojejunostomy may be performed.

OTHER GASTRIC CONDITIONS

Acute gastric dilatation

This condition usually occurs in association with pyloroduodenal disorders or postsurgery without nasogastric suction. The stomach, which may also be atonic, dilates enormously. Often the patient is also dehydrated and has electrolyte disturbances. Failure to treat this condition can result in a sudden massive vomit with aspiration into the lungs. The treatment is nasogastric suction, with a large-bore tube, fluid replacement and treatment of the underlying condition.

Trichobezoar and phytobezoar

Trichobezoar (hair balls) (Figure 63.34) are unusual and are virtually exclusively found in female psychiatric patients, often young. It is caused by the pathological ingestion of hair, which remains undigested in the stomach. The hair ball can lead to ulceration and gastrointestinal bleeding, perforation or obstruction. The diagnosis is made easily at endoscopy or, indeed, from a plain radiograph. Treatment consists of removal of the bezoar, which may require open surgical treatment. Phytobezoars are made of vegetable matter and found principally in patients who have gastric stasis. Often this follows gastric surgery.

Figure 63.34 Trichobezoar of the stomach in a girl aged 15 years.

Bezoars are masses of foreign material in the stomach or intestines of animals, and are relatively common. In some primitive communities a gastric bezoar from a goat is accredited with magical healing properties.

Foreign bodies in the stomach

A variety of ingested foreign bodies reach the stomach, and very often these can be seen on a plain radiograph. If possible, they should be removed endoscopically but, if not, most can be left to pass normally. Even objects such as needles, with which there is understandable anxiety, will seldom cause harm. In general, an object which leaves the stomach will pass spontaneously. In contrast, attempted removal at laparotomy can be very difficult as the object may be much more difficult to find than might be expected. Most adults who swallow foreign bodies have ill-defined psychiatric problems and may appear to relish the attention associated with serial laparotomies. The treatment should therefore be expectant and intervention reserved for patients with symptoms in whom the foreign body is failing to progress.

Volvulus of the stomach

Rotation of the stomach usually occurs around the axis and between its two fixed points, i.e. the cardia and the pylorus. In theory, rotation can occur in the horizontal (organoaxial) or vertical (mesenteroaxial) direction but, commonly, it is the former which occurs. This condition is usually associated with a large diaphragmatic defect around the oesophagus (paraesophageal herniation) (Figure 63.35). What commonly happens is that the transverse colon moves upwards to lie under the left diaphragm, thus taking the stomach with it, and the stomach and colon may both enter the chest through the eventration of the diaphragm. The condition is commonly chronic, the patient presenting with difficulty in eating. An acute presentation with ischaemia may occur. Endoscopically, it can be

Figure 63.35 Barium meal showing organoaxial volvulus of the stomach associated with eventration of the diaphragm.

extremely difficult to sort out the anatomy, and this is one situation in which the contrast radiograph is superior.

Treatment

If the problem is causing symptoms then surgical treatment is the only satisfactory approach. Traditionally, open surgery has been employed but this problem is suitable for laparoscopic treatment if appropriate skill is available. If there is a hernia, the sac and its contents (usually the stomach) should be reduced. The defect in the diaphragm should be closed, if necessary, with a mesh. It is advisable to separate the stomach from the transverse colon and then perform an anterior gastropexy to fix the stomach to the anterior abdominal wall. The results from this treatment are good.

CHAPTER
64

Bariatric surgery

LEARNING OBJECTIVES

To know and understand:

- What morbid obesity is
- Who is eligible for bariatric surgery
- What surgical procedures are currently available
- Outcomes and complications
- What the future holds for bariatric surgery

INTRODUCTION

Surgical management for obesity has been available for decades. The first recorded proper bariatric operation, the jejunoileal bypass (JIB), was described in 1954. The JIB was the most popular procedure in the 1960s but fell into disrepute because of various complications, some of which were lethal. To avoid these complications Edward Mason devised the vertical banded gastroplasty which after various iterations stood the test of time until he devised the gastric bypass which then became the gold standard in the United States. To improve on the older JIB operation, Nicola Scopinaro from Italy modified the procedure as a biliopancreatic diversion (BPD) which was further modified by Marceau with a duodenal switch. In the 1980s, gastric bands were introduced to the market, at first as non-adjustable then as adjustable bands.

The laparoscopic era heralded a paradigm shift in bariatric surgery such that all procedures are now able to be carried out laparoscopically. Open surgery has all but disappeared except for some complex revisional procedures. Furthermore, the growth in recent decades of obesity surgery has led to a much more professional approach to the subject with the establishment of a multidisciplinary team (MDT) for patient selection and follow up, emphasis on quality improvement and accreditation of surgeons and units as well as a constant search for more effective and safer surgical methods of treatment. There is now universal agreement that obesity surgery is better termed metabolic surgery because of its profound effects on the various hormones which affect insulin sensitivity.

CAUSES OF OBESITY AND EPIDEMIOLOGY

Obesity is a multifactorial metabolic disorder which essentially manifests itself as a surplus of unexpended energy stored as fat. The contributing factors include genetic predisposition, eating

disorders, psychological issues, poor diet, lack of exercise and comorbid conditions predisposing to obesity. The outcome of excess fat storage is often the development of a metabolic syndrome which drives the excess incidence of associated comorbidities. Table 64.1 shows the comorbidities associated with morbid obesity all of which can be improved by weight loss.

Morbid obesity is defined as a body mass index (BMI) equal to or greater than 40 kg/m² (Table 64.2). A patient with a BMI of 40 kg/m² is around 80 per cent above their ideal body weight. A 40-year-old woman with a BMI of 40 kg/m² has an excess mortality of 8–12 years and will die younger than her peer group with a normal BMI. As BMI increases further so does the incidence

Table 64.1 List of comorbidities associated with obesity which can be alleviated by surgical induced weight loss.

Comorbidity	
Metabolic syndrome	Type II diabetes mellitus
	High blood pressure
	Dyslipidaemia
Obstructive sleep apnoea	
Venous and lymphatic stasis	
Osteoarthritis

Pseudotumour cerebri (idiopathic intracranial hypertension)	
Poor quality of life	
Urinary stress incontinence	
Gastro-oesophageal reflux disease	

Nicola Scopinaro, born 1945. Professor of Surgery, University of Genoa, Italy. A charismatic figure and one of the most influential figures in the development of bariatric surgery.

Edward Mason, born 1920 (in the back seat of a taxi). Emeritus Professor of Surgery, University of Iowa, IA, USA. Best known as the 'father of obesity surgery'.

Table 64.2 Definition of body mass index (BMI).

Normal	BMI = 20–25 kg/m ²
Morbid obesity	BMI >40 kg/m ²
	BMI >35 kg/m ² with comorbidity

BMI = weight (kg)/height (m)².

of associated comorbidities and the chance of premature death. The cause of death usually results from advanced metabolic syndrome causing premature atherosclerosis and diabetes.

In the UK, 2 per cent of females and 0.8 per cent of males have a BMI >40 kg/m² while in the US these figures are much higher. The international trend is for obesity incidence to increase such that the definition of a normal BMI of 20–25 kg/m² has been called into question. The comorbidities caused by obesity have become one of the world's greatest health-care problems as we do not seem to be able to stop the increase in obesity levels despite educating the public.

Non-surgical treatment for morbid obesity usually involves the patient trying various diets and attempts at exercising more regularly as well as other lifestyle changes. This can be aided by slimming clubs, professional dietician advice, personal exercise trainers and some pharmacological agents. Sadly, for morbidly obese patients, these have a 97 per cent long-term failure rate which is the main driver for surgical means to deal with the disorder. Even after initially successful bariatric surgery there is always a trend for gradual weight regain over the long term. This requires the bariatric patient to continue to address diet and exercise requirements. It must always be emphasised to patients that bariatric surgery does not cure the obesity problem but is an adjunct to help them to manage the problem more readily.

RELEVANT ANATOMY AND PHYSIOLOGY

Most bariatric procedures are aimed at the stomach in an attempt to restrict the amount the patient can eat. Some of these procedures also add an element of gastric and small intestinal bypass to produce a degree of malabsorption. Experimentally there are also approaches trying neuromodulation of the vagus or gastric muscle in order to create increased satiety.

The stomach receives food and starts the digestive process by adding acid and pepsin during the titration process. The fundic area of the stomach also produces grehlin which is the only known hormone that stimulates appetite. During a meal levels of grehlin drop while between meals grehlin levels rise to stimulate the need to eat again. In addition, the stomach during filling undergoes adaptive relaxation mediated by the vagus so that it will accommodate food at a constant pressure. The jejunum and ileum also produce peptide hormones such as glucagon-like peptide-1 (GLP-1), peptide-YY (PYY) and cholecystokinin (CCK) which also have a role in stimulating the release of insulin and reducing appetite.

RATIONALE FOR OBESITY SURGERY

Obesity is dangerous to health due to the excess incidence of comorbidities that obese patients often develop, especially the metabolic syndrome. Many studies have suggested that

if weight loss is induced surgically this leads to improvement in various comorbidities which translates into increased life expectancy. The best study so far is the well-known Swedish Obese Subjects study, which started in 1987, where the investigators matched over 2000 surgically treated patients with 2000 medically treated patients and followed these cohorts up for 15 years. Essentially this research has demonstrated that surgically induced weight loss increases life expectancy, and ameliorates diabetes, hypertension, hyperlipidaemia, obstructive sleep apnoea and atherosclerosis rates. In addition, these workers also have demonstrated that bariatric surgery leads to an improved quality of life and the patient being more likely to be employed as well as costing the health service less money. There is also some evidence from these workers as well as others that bariatric surgery reduces the incidence of some cancers. All published expert reports have supported bariatric surgery as being justifiable, namely the National Institute for Health in the US and the National Institute for Clinical Excellence in the UK. It should also be emphasized to potential patients that obesity surgery is not cosmetic surgery – it is designed to prevent the comorbidities that obesity causes with the long-term aim to increase life expectancy and quality of life (Summary box 64.1).

Summary box 64.1

Rationale for surgery

- Increase life expectancy
- Decrease comorbidities
- Decrease health-care costs to society

One of the biggest issues with bariatric surgery is who will pay for it. Rationing is inevitable in countries with a socialised health-care system, which nowadays is our biggest challenge. Who takes priority – a 55-year-old man with multiple comorbidities who is costing the health service a considerable amount of money or a 25-year-old man who is morbidly obese but as yet has not developed any comorbidities? No one has a clear answer to this ethical dilemma although ideally they should both be offered surgery.

PATIENT SELECTION AND PREPARATION FOR SURGERY

The criteria for patient selection are universally agreed (Table 64.3) although the evidence base for them has never been clearly delineated. Indeed, many bariatric surgeons think they are too conservative and need to be revised in light of new knowledge. There will always be some exceptions to the guidelines but for most part they should be followed. There is also an increasing trend for bariatric surgery to be carried out in younger patients, especially those in the paediatric age group where it is becoming clear that delaying surgery to adulthood is detrimental to their health.

All surgical candidates should be seen by the bariatric MDT (Table 64.4). All patients need some dietetic assessment which may help to choose the correct operation for them. In addition, they must be seen by a physician with an interest in obesity to screen for endocrine disorders and to establish the degree of metabolic syndrome present. All patients should also

Table 64.3 Selection criteria for obesity surgery (based on the International Federation for Surgery of Obesity and the National Institute for Clinical Excellence).

Body mass index (BMI) >40 kg/m ² or BMI 35–39 kg/m ² with serious comorbid disease treatable by weight loss
Minimum of 5 years obesity
Failure of conservative treatment
No alcoholism or major untreated psychiatric illness
Avoid if likely to get pregnant within 2 years
Age limits 18–55 (relative)
Acceptable operative risk on preoperative assessment

Table 64.4 Obesity multidisciplinary team (MDT) – all with required bariatric training.

Surgeon with a bariatric training
Physician with a special interest in obesity
Dietician
Specialist bariatric nurse
Anaesthetist
Skilled theatre staff
Psychiatrist/psychologist with interest in eating disorders

have a psychological screen to determine whether there are unresolved issues to be dealt with either pre- or postoperatively.

The risks of bariatric surgery need particular attention when counselling patients as the global risk of perioperative death is around 1 per cent although it is much lower than this for some procedures, especially in fitter patients. Involvement of the family or carers in decision-making is also crucial (Summary box 64.2).

Summary box 64.2

Patient selection

- Follow national guidelines
- Need MDT assessment
- Patient must understand risk/complications

Preoperatively patients are generally put on a low carbohydrate diet for a minimum of 2 weeks to shrink the liver to allow for adequate working space to carry out the surgery. A preoperative baseline metabolic screen (Table 64.5) is also desirable to determine the levels of vitamins, minerals and micronutrients which are essential for health. It is well recognised that many bariatric patients preoperatively suffer from vitamin and micronutrient deficiencies, usually due to their poor diet.

SURGICAL TREATMENT

The choosing of the best surgical procedure for an individual patient is not an exact science. What is clear is that there is

Table 64.5 Preoperative nutrition screen.

All patients	Full blood count, urea and electrolytes, liver function tests
	Fasting lipid profile
	Fasting glucose, HbA1C (if diabetic)
	Vitamins A, D and E
	Parathyroid hormone
Bypass patients	Magnesium, calcium and phosphate
	Ferritin, vitamin B12, folate and coagulation screen
	Zinc, selenium, copper and C-reactive protein

no perfect operation free of side effects or complications. Some procedures are more effective than others albeit at the cost of higher perioperative rates of morbidity and mortality. It is unclear what the end point of bariatric surgery should be: is it maximum weight loss regardless of risk or just enough weight loss to alleviate comorbidities at minimum risk? Intuitively, it should be maximum weight loss with least risk and side effects, which requires a very detailed discussion of the options available with each individual patient.

As with other high-risk surgical procedures there is a volume–outcome effect thus it behoves any commissioner of bariatric services to fund only established high-volume centres in order to reduce complications and improve outcomes.

CURRENT SURGICAL OPTIONS

The surgical options have varying degrees of gastric restriction from pure (banding) to least (standard biliopancreatic diversion (BPD)). Varying degrees of malabsorption also pertain from none (banding) to severe (BPD). All procedures are usually carried out laparoscopically and increasingly through fewer access ports as instrumentation and techniques improve. With appropriate training some procedures can be carried out through a single umbilical incision although the future role of this approach is as yet unclear. Furthermore, some surgeons are now experienced at carrying out some procedures transvaginally leaving no abdominal scars at all!

Gastric banding

Around half of all surgical procedures in many countries are gastric bands which involves putting an adjustable band around the upper stomach leaving a small pouch just below the cardia (Figure 64.1). The degree of restriction can be controlled by the amount of fluid injected into the subcutaneous port. This operation is especially popular in Australia where excellent results are obtained. The perception that the band is reversible is important to some patients (although in reality it is a disadvantage). Gastric banding is certainly the least risky procedure (0.1 per cent perioperative mortality) as it does not involve cutting any stomach or bowel and is a relatively easy operation to perform in most patients who have a BMI <50 kg/m².

Most patients can expect to lose around 45–50 per cent of their excess weight, especially if the quality of follow up is intensive. However, there is a wide variation in results with

Figure 64.1 Gastric band.

some patients obtaining poor weight loss eventually requiring a revisional procedure. Furthermore, bands can fail due to prolapse of the stomach through the band or the band can slip up or down from its initial position. Bands can also erode into the stomach. Although the incidence of these complications is relatively low (<5 per cent) up to 30 per cent of patients are deemed long-term failures due to insufficient weight loss. It may be that these patients have been poorly selected in the first place or the quality of their follow up has not been very good.

One disadvantage of the gastric band is the need for continual band adjustments in the early postoperative period and occasional long-term adjustments. It is generally considered a labour-intensive procedure which requires a lot of patient compliance to get good results. Another disadvantage of the gastric band is that when a revisional procedure is indicated it is a much higher-risk procedure due to adhesions and gastric wall thickening.

However, gastric banding has a place in properly selected patients who have the correct attitude and understanding of the postoperative requirements. In selected patients a band can even be inserted as a day-case procedure. It should generally be avoided in binge eating patients and those whose eating habits involve excessive sweets and chocolate.

Sleeve gastrectomy

This relatively new operation requires less postoperative monitoring as it does not require any adjustments although it is a riskier procedure than gastric banding (0.2 per cent operative mortality). The long staple line can leak despite various manoeuvres to avoid leakage, such as applying reinforcing material and/or gluing. Another attraction of this procedure is that as it removes most of the ghrelin-secreting area of the stomach it may have a beneficial effect on reducing appetite (Figure 64.2).

Around 65 per cent excess weight loss can be expected at two years which is as good as gastric bypass without any malabsorption issues. However, there is a tendency for the sleeve to expand over time. A resleeving procedure is well described or alterna-

tively it is relatively straightforward to convert the procedure to a gastric bypass or a BPD with a duodenal switch. Indeed, many bariatric surgeons believe that in patients with a BMI >50 kg/m² who want a gastric bypass, it is safer to do a sleeve gastrectomy first and convert only those patients who regain weight to a gastric bypass. The exact percentage of how many patients might require a second procedure is not yet clear but is probably around 10–20 per cent depending on patient selection. Thus, the concept of bariatric surgery as a staged procedure has been mooted with the first stage being a sleeve gastrectomy and the second a gastric bypass or BPD with a duodenal switch. The second stage in most cases will not be needed.

The true place for sleeve gastrectomy as a primary bariatric procedure is still unclear and more long-term data are needed. Despite this, the frequency of this procedure is accelerating at a remarkable rate largely because of the relative technical ease of doing the procedure, the lack of potential malabsorption problems and the option of doing a relatively safe second-stage procedure if needed.

Roux-en-Y gastric bypass

The gastric bypass is a very effective weight loss procedure but is performed with a myriad of technical variations making comparisons difficult. However, overall it produces 65–75 per cent excess weight loss albeit at a higher risk of around 0.5 per cent perioperative mortality.

Gastric bypass is a very effective operation for alleviating and even curing type II diabetes – the result being almost immediate and independent of weight loss. There are two major theories as to how this happens (Table 64.6), given that other bariatric procedures such as banding and sleeve gastrectomy are dependent on weight loss to resolve the diabetes. Over 80 per cent of patients will have their diabetes permanently resolved (Table 64.7).

There are many variations in the actual gastric bypass technique, e.g. antecolic versus retrocolic Roux limb placement, varying alimentary and biliary limb lengths, additional banding of the gastrojejunal anastomosis to prevent dilatation, varying methods of doing the gastrojejunal anastomosis and varying methods of closing potential hernia spaces (Figure 64.3). There is a need to consolidate knowledge about the outcomes of these variations in order to standardise the procedure.

Although weight loss is generally very good the downside of this procedure is the need for careful postoperative metabolic

Figure 64.2 Sleeve gastrectomy.

follow up to avoid deficiency syndromes. Additional multivitamins, iron and calcium are needed for all patients as well as vitamin B12 administration. Some surgeons also recommend periodic bone densitometry measurements to avoid premature osteoporosis.

Biliopancreatic diversion – with or without a duodenal switch

This procedure, which produces the most malabsorption of all operations, is the most effective with 75–85 per cent excess weight loss but at the expense of the highest perioperative mortality of 1–2 per cent. Additionally as time goes by, if the patient does not adhere to their vitamin and micronutrient supplementation regime they are at severe risk of many deficiency syndromes. Furthermore, due to the extreme malabsorption these operations produce there is a need for a high protein intake of around 90 g/day which many patients find difficult. If this is not achieved then protein calorie malnutrition can be a problem. In correctly selected patients however, the BPD can be very effective, especially in those patients with a very high BMI. A BPD also has the same rapid effect as a gastric bypass for alleviating diabetes independent of weight loss (Tables 64.6 and 64.7).

The duodenal switch variation of the BPD was designed to reduce the need for taking vitamin B12 and reduce the incidence of anastomotic strictures at the gastrojejunal anastomosis. In the standard BPD, approximately two-thirds of the distal stomach is removed while in the duodenal switch variation there is a vertical sleeve gastrectomy. In the duodenal switch variation, the anastomosis is made to the first part of the duodenum rather than the stomach as in the standard BPD. The limb lengths also vary, as shown in Figure 64.4. In reality, there is very little difference between these two procedures in terms of weight loss and

long-term complications despite some assertions to the contrary (Summary box 64.3).

Summary box 64.3

Established surgical options

- Restrictive
 - Adjustable gastric banding
 - Sleeve gastrectomy
- Bypass
 - Proximal gastric bypass
 - BPD ± duodenal switch

RESULTS

When discussing results of bariatric surgery there is an immediate problem in defining success. Traditionally it has been considered as losing at least 50 per cent of the excess weight in the first 12–24 months. The excess weight of a patient is their current weight minus their ideal body weight (at BMI 25 kg/m²). For a given procedure that removes say 50 per cent of excess weight, the higher the initial BMI of the patient the more weight is removed but the patient may still be considerably overweight after surgery compared to a lower BMI patient. Furthermore, many comorbidities are improved with only 10–20 per cent of excess weight loss thus the end point of removing as much weight as possible may not always be necessary from a health and longevity point of view. Other outcomes such as improved quality of life may also be as important. In general terms, however, most surgeons strive for an effective operation which is usually perceived as reducing as much weight as possible for the given risk of the procedure. In addition, it should also resolve or ameliorate any of the comorbidities which are linked to obesity (Table 64.1). Table 64.7 shows the usual outcomes for bariatric procedures.

While there is a spectrum of weight loss results between the various procedures there is also a variation in weight loss for each individual procedure which is usually a function of patient selection and postoperative follow up. For example, restrictive procedures are notorious for good early results but as time goes by the patient learns to cheat more effectively, eats more soft calories and becomes complacent about exercise. This results in weight regain which is always difficult to manage and in some cases will result in revisional surgery which is always more risky than a primary procedure. In addition, patients will often ‘move

Table 64.6 Theories on mechanisms of how a gastric bypass/biliopancreatic diversion ameliorates diabetes.

Foregut hypothesis	Bypass of proximal duodenum and jejunum reduces stimulated secretion of anti-incretin factors which normally inhibit insulin secretion thus allowing the unopposed effects of incretins to stimulate insulin secretion
Hindgut hypothesis	Rapid delivery of small bowel content into the distal jejunum and ileum exaggerates stimulated incretin (glucagon-like peptide-1 and peptide-YY) release which stimulates insulin secretion

Table 64.7 Outcomes from bariatric procedures.

	Restrictive (bands, sleeve gastrectomy)	Combined gastric bypass	Malabsorptive BPD with or without a duodenal switch
Excess weight loss (%)	48–68	62	72
Resolution of type 2 diabetes (%)	48–72	84	98
Resolution of hypertension, (%)	28–73	75	81
Improvement in dyslipidaemia (%)	71–81	94	100
Operative mortality (%)	0.1	0.5	1.10

the goal posts' wanting a better result than the surgery promises. Thus, a clear understanding of the end point of surgery must be agreed before embarking on any procedure, i.e. amount of weight loss or resolution of comorbidities or, usually, a combination of both. If this is written down and agreed preoperatively this avoids misunderstandings postoperatively.

It behoves the surgeon to get the operation right the first time for an individual patient after a thorough understanding of what risks they are prepared to take for a particular outcome. This will

vary from patient to patient. Those patients who are very risk averse, often young with young children, will understandably often want an operation with the least postoperative mortality even though it may not result in as much weight loss as another more risky procedure. Conversely, a patient without children who is older and much heavier may be keen to undergo a more risky procedure to maximise their weight loss. It is a matter of considerable judgement on both the patient and surgeon's part to decide what is the most suitable procedure for a given patient. Discussion at a bariatric MDT is always desirable in order that every member of the bariatric team has a chance to express their views about the suitability of any particular procedure for the patient in question.

COMPLICATIONS

Carrying out surgery in obese patients generally is more risky than surgery in lean patients no matter what type of surgery is contemplated. Obese patients are more likely to suffer from cardiorespiratory comorbidities which increase surgical complications. Furthermore, they are often hypercoagulable with an increased risk of deep-vein thrombosis and pulmonary embolism. Most of the general risks of surgery, such as bleeding and infection, are also more likely to occur. The specific risks in relation to the actual surgical procedure will vary from procedure to procedure and are listed in Table 64.8.

Perioperative mortality should be minimal but is higher in those patients with the most severe comorbidities. Severe unstable cardiovascular disease is an absolute contraindication to bariatric surgery. Super-obese (BMI >50 kg/m²) males also have a higher risk of perioperative mortality as well as patients with a past history of pulmonary embolism. For the latter a prophylactic

Figure 64.4 (a) Standard biliopancreatic diversion (BPD); (b) BPD with duodenal switch variation.

Table 64.8 Risks of bariatric procedures.

Risk	
General risks of bariatric surgery	Bleeding
	Infection
	Deep vein thrombosis (± pulmonary embolism)
	Accidental bowel perforation
	Perioperative mortality (see Table 64.6)
Risks of specific bariatric procedures	Internal herniation (gastric bypass and BPD)
	Staple line/anastomotic leak (gastric bypass, sleeve gastrectomy, BPD)
	Band slippage/erosion
	Pouch dilatation (gastric band, gastric bypass, sleeve gastrectomy)
Long-term risks of all bariatric surgery	Protein calorie malnutrition
	Vitamin and micronutrient depletion syndromes
	Weight regain

BPD, biliopancreatic diversion.

preoperative caval filter should be considered. Even if there is no history of deep-vein thrombosis, a pulmonary embolism is still a leading cause of perioperative mortality despite the usual prophylactic precautions of graded calf compression stockings, intraoperative calf compression, intraoperative low molecular weight heparin, early mobilisation and extended postoperative low molecular weight heparin administration.

Leaks from resection margins, anastomoses or off-camera injuries are also feared along with internal hernias which appear to be more prevalent after laparoscopic surgery. The key message is that when a complication is suspected it is important to carry out investigations immediately and not delay as morbidly obese patients often have relatively few clinical signs and symptoms despite overt peritonitis. Often this investigation may take the form of immediate return to theatre and laparoscopy to assess the situation rather than wasting time doing other investigations.
